Super-replication of financial derivatives via convex programming

Nabil Kahalé *

First version: November 7, 2012
This version: March 22, 2016

Abstract

We give a method based on convex programming to calculate the optimal super-replicating and sub-replicating prices and corresponding hedging portfolios of a financial derivative in terms of other financial derivatives in a discrete-time setting. Our method produces a model that matches the super-replicating (or sub-replicating) price within an arbitrary precision and is consistent with the other financial derivatives prices. Applications include robust replication in terms of call prices with various strikes and maturities of forward start options, volatility and variance swaps and derivatives, cliquets calls, barrier options, lookback and Asian options. Numerical examples show that, in some cases, the best super-replicating and/or sub-replicating prices are within 10% of the price obtained by a standard model, but considerably differ from it in other cases. Our method can incorporate bid-ask spreads, interest rates and dividends and various limitations to the diffusion model.

Keywords: Model risk, robust replication, robust hedging, convex programming, financial derivatives.

1 Introduction

Several models based on local volatility, stochastic volatility or jump diffusion (see, e.g., (Hull 2012)) have been used to price financial derivatives. However, even if these models exactly fit the current market prices of liquid financial products, such as vanilla call and put options, they may produce different prices for other products such as barrier options (Britten-Jones and A. Neuberger 2000). This gives rise to model risk in the pricing of financial derivatives, of which practitioners are well aware (see (Committee on Banking Supervision 2009, p. 29)). This model risk can be assessed through the calculation of model-independent bounds on the derivative price: the larger the gap between the upper and lower bound, the larger the risk. Another possible application of model-independent bounds comes from the observation that if a bank sells (resp. buys) a derivative at a model-independent upper-bound (resp. lower-bound) on its price, it can realize a non-negative net profit by using proper hedging, independently of the future underlying securities behavior. The range of possible arbitrage free prices for a given derivative security $\psi$ is large in general (Carassus, Gobet and Temam 2007) but can be narrowed if the prices of liquid derivatives, such as call prices, are known at time 0. Bounds on option prices in terms of other financial derivatives prices have been derived in the literature in a static setting as well as in a dynamic setting, i.e. when dynamic trading in the stock is allowed at future times.

In a static setting, (Boyle and Lin 1997) have derived a semi-definite upper-bound on a call on the maximum of several assets in terms of their means and correlations. (Bertsimas and Popescu 2002, Gotoh and Konno 2002) have used semi-definite programming to optimally

*ESCP Europe and Labex ReFi, 79 avenue de la République, 75011 Paris, France; e-mail: nka-
hale@escpeurope.eu.
super-replicate call options in single-period markets on a single asset given several moments of the underlying asset. Tight bounds on prices of basket options (Hobson, Laurence and Wang 2005a, Hobson, Laurence and Wang 2005b, Laurence and Wang 2005, d’Aspremont and El Ghaoui 2006) and on spread options (Laurence and Wang 2008, Laurence and Wang 2009) have been established in terms of prices of vanilla options with the same maturity.

In a dynamic setting, optimal bounds on specific options have been previously derived under certain conditions. When interest rates are null, tight model-independent bounds on lookback and barrier options have been obtained (Hobson 1998, Brown, Hobson and Rogers 2001b, Brown, Hobson and Rogers 2001a, Hobson and Pedersen 2002, Cox and Oblój 2011a, Cox and Oblój 2011b, Galichon, Henry-Labordèere and Touzi 2014, Henry-Labordèere, Obloj, Spoida and Touzi 2013) in terms of call prices. Under a continuity assumption on the stock price, numerical schemes for robust hedging of financial derivatives have been given (Bonnans and Tan 2011, Tan and Touzi 2013) in terms of a continuum set of call prices, robust pricing of a continuously-monitored variance swap given prices for a finite number of co-maturing call options has been obtained (Davis, Obloj and Raval 2014), and optimal bounds on continuously-monitored variance options have been derived analytically (Cox and Wang 2013). Explicit bounds on discretely-monitored variance swaps (Kahale 2014, Hobson and Klimmek 2012) have been established in terms of a continuum set of call prices with the same maturity and shown to be optimal when the number of time-steps goes to infinity. (Henry-Labordere and Touzi 2013) have derived optimal bounds on variance swaps monitored at \( t_i \) when call prices are known for maturities \( t_i, 1 \leq i \leq m \), and all strikes. A tight but non-constructive upper bound (Hobson and Neuberger 2012) on at the money forward-start options and, under certain conditions, a tight and explicit lower bound (Hobson and Klimmek 2015) have been obtained in terms of a continuum set of call prices.

Most previous derivations of explicit bounds construct explicitly associated hedging strategies. Also, they often identify explicit scenarios that lead to the extremum prices. However, explicit optimal bounds on path-dependent derivatives that we are aware of make at least one of the following simplifying assumptions: interest rates are null, call prices are known for a continuum set of strikes, or the underlying variables prices follow a continuous process. These assumptions do not hold in practice, though, and may introduce an important bias in the pricing of a financial derivative. For instance, the price of a continuously-monitored variance swap, when jumps in the stock prices are allowed, may significantly differ from the price obtained under the continuity assumption (Demeterfi, Derman, Kamal and Zou 1999, Broadie and Jain 2008, Carr and Wu 2009, Carr, Lee and Wu 2012). Also, in practice, variance swaps are discretely monitored, but it has been often been assumed in the literature that they are continuously monitored, which introduces another source of bias as shown in (Broadie and Jain 2008). Furthermore, optimal explicit bounds are only known for specific options and not known in general for a portfolio of options, even in two-periods markets. This can be explained by noting that robust super-replication is closely related (Henry-Labordere and Touzi 2013) to the optimal transportation problem, for which no explicit solutions are known in general.

This paper gives a unified methodology based on convex programming to calculate the best super-replicating and sub-replicating prices and corresponding hedging portfolios of a financial derivative \( \psi \) in terms of prices of a finite set of \( l \) liquid derivatives. Super-replicating (or sub-replicating) strategies for \( \psi \) consist of static positions in a zero-coupon bond and in the \( l \) derivatives at time 0 combined with dynamic trading in \( d \) underlying liquid securities. We assume that interest rates are deterministic and work in a multi-period setting but do not make any continuity assumptions on the underlying variables. Under certain conditions, we show the convex program can be solved efficiently for a large class of financial derivatives. Furthermore, our method produces a model that matches the super-replicating (or sub-replicating) price within an arbitrary precision and is consistent with the other financial derivatives prices. Applications include the calculation of the best super-replicating and sub-replicating prices in
terms of call options with different strikes and maturities of a wide variety of derivatives such as

- discretely-monitored, standard and generalized variance swaps including cliquet calls and corridor variance swaps
- discretely-monitored volatility swaps and volatility derivatives
- discretely-monitored Asian options
- discretely monitored lookback and barrier options.

We are not aware of previous model-independent optimal bounds for any of these problems without the simplifying assumptions mentioned earlier. In particular, we give the first optimal bounds on discretely-monitored variance and volatility swaps in terms of a finite set of call prices without any continuity assumption on the stock, and the first optimal bounds on the price of arithmetic Asian options. Model-independent bounds for prices of Asian options have been previously derived (Simon, Goovaerts and Dhaene 2000, Albrecher, Mayer and Schoutens 2008), but they are not optimal. We also give the first optimal bounds on discretely monitored lookback and barrier options in terms of a finite set of call prices without assuming interest rates to be null. Finally, we give optimal robust bounds on forward start options. In (Beiglböck, Henry-Labordère and Penkner 2013), optimal model-independent bounds for forward-start options in terms of a finite set of call prices are calculated in a discrete-state setting using linear programming, but no bound is given on the discretization error. In addition, our convex program can be easily adapted to calculate the best model-free bounds on a financial derivative when bid and ask prices of the liquid financial derivatives are not equal, or the size of the jumps the assets can take are restricted.

A method based on linear programming with a large number of constraints is described in (Henry-Labordère 2013) to robust hedging of derivatives. However, this method requires the amount of basic securities held in a dynamic hedging position to be a function of a certain type (e.g. a polynomial) of the securities values. It also assumes the securities paths to belong to a certain grid generated by a Monte Carlo simulation scheme, and requires the knowledge of a continuum set of call options prices. No estimate on the errors due to these requirements is given in (Henry-Labordère 2013).

In line with previous literature on robust bounds on derivatives that depend on the underlyings’ values on a finite set of time-steps (see, e.g., (Simon, Goovaerts and Dhaene 2000, Albrecher, Mayer and Schoutens 2008, Kahalé 2014, Hobson and Neuberger 2012, Hobson and Klimmek 2012, Hobson and Klimmek 2015, Beiglböck, Henry-Labordère and Penkner 2013, Henry-Labordere and Touzi 2013)), we use a discrete-time model with an infinite state-space without reference to a single prior measure. We only use risk-neutral probabilities with finite support, as these are sufficient to derive optimal model-independent bounds in our framework (see Theorem 3.2, and (Kahalé 2010) for related results). In our numerical applications, we discretize the state-space and show how to bound the discretization error.

The remainder of the paper is organised as follows. Definitions and preliminary results are given in Section 2. Section 3 presents our convex program and shows that, under suitable conditions, it can be solved using a subroutine described in Section 4. Several examples including numerical applications are discussed in Section 5. Our numerical examples assume the call prices on a stock are given by the Black-and-Scholes formula with a constant volatility for one or two maturities, but do not assume the stock to follow a log-normal process with a constant volatility. Section 6 discusses various extensions of our method. Section 7 contains concluding remarks. Most proofs are contained in the appendix.
2 Preliminaries

2.1 The modelling framework

We aim to establish model-independent bounds in a simple setting inspired from the classical theory of multi-period markets (see (Pliska 2005, Chapter 3) and (Follmer and Schied 2004, Ch. 5)). For simplicity, we assume for now that interest rates and dividends are null. Section 6 shows how to incorporate interest rates and dividends in our framework. An $m$-period market $\mathcal{M}$ consists of $d$ basic securities on a non-empty sample space $\Omega$. The securities prices $S_0^i, \ldots, S_0^d$ at time-step 0 are known constants. The price $S_i^k$ of security $k$ at time-step $i$, $0 \leq i \leq m$, is a function from $\Omega$ to $\mathbb{R}$. Assume now that $S_0^i$ and of positions in the derivatives $\phi_j$, $1 \leq j \leq l$, at time-step $i - 1$ and sell them at time-step $i$. Denote by $\xi_i$ the $d$-dimensional vector $(\xi_i^k)$, $1 \leq k \leq d$. The vector $\xi_i$ is an arbitrary function of the past values of the $d$ securities, i.e. it is a function of $S_j^k$, $1 \leq k \leq d$, and $1 \leq j \leq i - 1$. The cumulative payoff of the investor, which we call a gains function, is $\sum_{i=1}^{m} \xi_i^T \left(X_i - X_{i-1}\right)$. We assume that zero-coupon bonds maturing at time-step $m$ are liquid at time 0. A financial derivative is a function from $\Omega$ to $\mathbb{R}$. A finite-support probability on $\Omega$ is a non-negative function on $\Omega$ that takes positive values on a finite number of elements and that sums up to 1.

**Definition 2.1.** A risk-neutral probability is a finite-support probability $P$ on $\Omega$ such that $E_P(g) = 0$ for any gains function $g$.

2.2 The super-hedging cost

Consider a financial derivative $\psi$. We say that a financial derivative $\psi'$ super-replicates $\psi$, and write $\psi \leq_g \psi'$, if there is a gains function $g$ such that $\psi(\omega) \leq \psi'(\omega) + g(\omega)$ for $\omega \in \Omega$. Thus, the payoff of a properly hedged long position in $\psi'$ is always no less than the payoff of $\psi$. Consider a portfolio of $\gamma$ bonds that pay 1 at time-step $m$. The portfolio cost is $\gamma$. Define the super-hedging cost $c(\psi) = c(\psi; \mathcal{M})$ of $\psi$ as

$$c(\psi) = \inf \{ \gamma : \gamma \in \mathbb{R}, \psi \leq_g \gamma \},$$

(2.1)

with the usual convention that $\inf(\emptyset) = \infty$. Thus $c(\psi)$ is the infimum price of a bond that super-replicates $\psi$. Let $\mathbb{P}$ be the set of risk-neutral probabilities. Since $E_P(\psi) \leq \gamma$ for any risk-neutral probability $P$ and any $\gamma$ such that $\psi \leq_g \gamma$,

$$\sup_{P \in \mathbb{P}} E_P(\psi) \leq c(\psi).$$

(2.2)

2.3 The super-replicating price

Assume now that $\phi = (\phi_1, \ldots, \phi_l)$ is a vector of financial derivatives that trade at prices $\pi_1, \ldots, \pi_l$ at time-step 0. Let $\beta = (\beta_1, \ldots, \beta_l)$ be a vector of length $l$. The portfolio $\beta^T \phi + \gamma$ consists of $\beta_j$ derivatives $\phi_j$, $1 \leq j \leq l$, and of $\gamma$ bonds that pay 1 at time-step $m$. It has a cost of $\beta^T \pi + \gamma$, where $\pi = (\pi_1, \ldots, \pi_l)$. Define the best super-replicating price $\pi_{\sup} = \pi_{\sup}(\psi, \phi; \mathcal{M})$ as

$$\pi_{\sup} = \inf_{(\beta, \gamma) \in V_0} \beta^T \pi + \gamma,$$

(2.3)

where

$$V_0 = V_0(\psi, \phi; \mathcal{M}) = \{(\beta, \gamma) \in \mathbb{R}^l \times \mathbb{R} : \psi \leq_g \beta^T \phi + \gamma \}.$$ 

In other words, $\pi_{\sup}$ is the infimum cost of a super-replicating portfolio composed of a bond and of positions in the derivatives $\phi_j$, $1 \leq j \leq l$. Define $V = V(\psi, \phi; \mathcal{M})$ as

$$V = \{(\beta, \gamma) \in \mathbb{R}^l \times \mathbb{R} : c(\psi - \beta^T \phi) \leq \gamma \}.$$ 

(2.4)
If \((\beta, \gamma) \in V_0\) then \(\psi - \beta^T \phi \leq \gamma\) and so, by (2.1), \((\beta, \gamma) \in V\). Conversely, it follows from (2.1) that, if \((\beta, \gamma) \in V\) and \(\gamma' > \gamma\), then \(\psi - \beta^T \phi \leq \gamma'\), and so \((\beta, \gamma') \in V_0\). Thus, \(V_0 \subseteq V \subseteq \overline{V}\), where \(\overline{V}\) is the closure of \(V_0\), and (2.3) can be rewritten as

\[
\pi_{\text{sup}} = \inf_{(\beta, \gamma) \in V} \beta^T \pi + \gamma. \tag{2.5}
\]

Note that

\[
V \subseteq \{(\beta, \gamma) \in \mathbb{R}^l \times \mathbb{R} : E_P(\psi) \leq \beta^T E_P(\phi) + \gamma \text{ for } P \in \mathbb{P}\}. \tag{2.6}
\]

This is because the RHS of (2.6) is closed and contains \(V_0\), and so it contains \(V\).

**Example 2.1.** Assume \(m = 2\), \(d = l = 1\), and the basic security is a stock valued at \(S_i\) at time-step \(i\), \(0 \leq i \leq 2\), with \(\phi_1 = \max(S_2 - K, 0)\) and \(\psi = \max((S_1 + S_2)/2 - K, 0)\). As

\[
\psi \leq \frac{1}{2}1_{i \geq K}(S_1 - S_2) + \phi_1,
\]

\(\pi_{\text{sup}}\) is upper-bounded by the price of \(\phi_1\).

**Remark 2.1.** An optimal sub-replicating price and strategy for \(\psi\) can be obtained by negating an optimal super-replicating price and strategy for \(-\psi\).

Throughout the rest of the paper, the running time refers to the number of arithmetic operations. Denote by \(0_k\) the null vector and by \(1_k\) the all-one vector in \(\mathbb{R}^k\), and denote by \(e_i\) the vector whose \(i\)-th coordinate is 1 and remaining coordinates are null.

### 3 Super-replication as a convex program

#### 3.1 General assumptions

We assume throughout this section that we are given positive real numbers \(\delta \leq 1/2\) and \(q\) such that

**A1.** \(c(\psi - \beta^T \phi)\) is upper-bounded by \(q\) for \(||\beta|| \leq \delta\).

**A2.** For any element \(\pi'\) of the set \(\bigcup_{i=1}^{l} \{\pi + \delta e_i, \pi - \delta e_i\}\), there is a risk-neutral probability \(P\) with \(E_P(\phi) = \pi'\) and \(-q \leq E_P(\psi)\).

**A3.** For \(\beta \in \mathbb{R}^l\), there is a risk-neutral probability \(P\) such that

\[
c(\psi - \beta^T \phi) = E_P(\psi - \beta^T \phi), \quad (3.1)
\]

and a subroutine that, on input \(\beta\), calculates \(c(\psi - \beta^T \phi)\) and \(E_P(\phi)\) in finite time \(T\).

Assumptions A1, A2 and A3 will be used to bound the running time of our convex program (see Theorem 3.2). Each time we will use Theorem 3.2 in the examples of Section 5, we will first prove that these assumptions hold by discretizing the state-space and using techniques developed in Sections 4 and 5. Assumption A1 implies that \((0_l, q) \in V\) and so, by (2.5), \(\pi_{\text{sup}} \leq q\). Note that if \(\pi'\) belongs to \(\{\pi + \delta e_i, \pi - \delta e_i\}\), then \(\pi\) and \(\pi'\) have the same coordinates expect for the \(i\)-th coordinate, and \(||\pi_i - \pi'_i|| = \delta\). Assumption 2 holds under certain no-arbitrage conditions (see, e.g. (Kahale 2010, Theorem 4.6)), but will be shown directly in our examples. On the other hand, Assumption A3 implies that there is no duality gap in (2.2) for the derivative \(\psi - \beta^T \phi\). The performance of our super-replication algorithm depends to a large extent on \(T\) (see Theorem 3.2, and Section 5), both in theory and in practice. When the state-space is finite and under a geometric condition (see Assumption A4), Section 4 shows that there is no duality gap in (2.2) for a class of derivatives, and gives a construction of the subroutine in Assumption A3.

**Remark 3.1.** If \(c(-\psi)\) is upper-bounded by a real number \(q'\) then, by (2.2), \(-q' \leq E_P(\psi)\) for \(P \in \mathbb{P}\).
3.2 The convex program

We first show that

\[ V = \{(\beta, \gamma) \in \mathbb{R}^l \times \mathbb{R} : E_P(\psi) \leq \beta^T E_P(\phi) + \gamma \text{ for } P \in \mathbb{P} \}. \] (3.2)

By (2.6), the RHS of (3.2) contains \( V \). Conversely, assume that \( (\beta, \gamma) \) belongs to the RHS of (3.2). By Assumption A3, there is \( P \in \mathbb{P} \) such that \( c(\psi - \beta^T \phi) = E_P(\psi - \beta^T \phi) \), and so \( c(\psi - \beta^T \phi) \leq \gamma \). Hence, \( (\beta, \gamma) \in V \).

Thus \( V \) is a convex set and (2.5) is a convex program since it implies that \( \pi_{\sup} \) is the infimum of a linear function over a convex set. Convex programs over bounded sets that admit a separation oracle can be solved efficiently under conditions stated in Subsection 3.4. Note that \( V \) is unbounded since \( (0, \gamma) \in V \) for \( \gamma \geq q \), but (2.5) can be rewritten as

\[ \pi_{\sup} = \inf_{(\beta, \gamma) \in V'} \beta^T \pi + \gamma, \]

where

\[ V' = \{(\beta, \gamma) \in V : \beta^T \pi + \gamma \leq q + 1\}. \]

Lemma 3.1 shows that \( V' \) is bounded. For the rest of the paper, let \( R_0 = (2q + 1)/\delta \) and

\[ R_1 = 4(1 + q)\sqrt{l}(1 + ||\pi||). \]

Lemma 3.1. Let

\[ \mathcal{E} = \{(\beta, \gamma) \in \mathbb{R}^l \times \mathbb{R} : -q \leq \beta^T (\pi + \delta e_i) + \gamma \text{ for } 1 \leq i \leq l\}, \]

\[ \mathcal{E}' = \mathcal{E}'(l, \pi, q, \delta) = \{(\beta, \gamma) \in \mathcal{E} : \beta^T \pi + \gamma \leq q + 1\}. \]

Then \( V \subseteq \mathcal{E} \), \( V' \subseteq \mathcal{E}' \) and, for \( (\beta, \gamma) \in \mathcal{E}' \), \( ||\beta||_\infty \leq R_0 \) and \( ||(\beta, \gamma)|| \leq R_1 \). Furthermore, \( V' \) contains the ball of radius \( \delta(1 + ||\pi||)^{-1} \) centered at \((0, q + 1)\).

3.3 A separation oracle for \( V' \)

A separation oracle for a convex set \( C \subseteq \mathbb{R}^k \) is a subroutine with the following property. The oracle accepts as input any vector \( y \in \mathbb{R}^k \). If \( y \in C \) the oracle returns a ”Yes”, whereas if \( y \notin C \) the oracle returns a vector \( a \in \mathbb{R}^k - \{0\} \) such that \( a^T y \leq a^T x \) for any \( x \in C \).

Proposition 3.1. \( V' \) admits a separation oracle that runs in \( T + O(1) \) time, where \( T \) is the running time of the subroutine in Assumption A3. On any input \( (\beta, \gamma) \in \mathbb{R}^l \times \mathbb{R} \), the oracle either returns a ”Yes”, or returns one of the two vectors \( -(\pi, 1) \) or \( (E_P(\phi), 1) \), where \( P \in \mathbb{P} \) is such that \( \beta^T E_P(\phi) + \gamma \leq E_P(\psi) \).

Proof. On input \( (\beta, \gamma) \in \mathbb{R}^l \times \mathbb{R} \), the separation oracle for \( V' \) runs through the following steps.

1. Let \( a_0 = (\pi, 1) \). If \( a_0^T (\beta, \gamma) > q + 1 \), the oracle returns \( -a_0 \). This is a valid return since \( a_0^T (\beta', \gamma') \leq q + 1 \) for \( (\beta', \gamma') \in V' \), and \( (\beta, \gamma) \notin V' \).

2. Else, calculate \( c(\psi - \beta^T \phi) \) via the subroutine in Assumption A3. If \( c(\psi - \beta^T \phi) \leq \gamma \) the oracle returns a ”Yes”.

3. Else, use the subroutine in Assumption A3 on input \( \beta \) to calculate \( a = (E_P(\phi), 1) \), where \( P \) is a risk-neutral probability such that (3.1) holds. By (3.1), \( \gamma \leq E_P(\psi - \beta^T \phi) \) and so \( a^T (\beta, \gamma) \leq E_P(\psi) \). On the other hand, (3.2) implies that \( E_P(\psi) \leq a^T (\beta', \gamma') \) for \( (\beta', \gamma') \in V \). Hence \( a^T (\beta, \gamma) \leq a^T (\beta', \gamma') \). The oracle returns \( a \).
3.4 Cutting plane algorithms

We now show how to solve the convex program (3.3) using a cutting plane algorithm. We assume throughout this subsection that C is a convex subset of \( \mathbb{R}^k \) that contains a ball of radius \( r \) that is contained in the ball \( B(0, R) \) of radius \( R \) centered at 0, and that \( C \) admits a separation oracle. We describe a generic cutting plane algorithm (see (Grötschel, Lovász and Schrijver 1981, Atkinson and Vaidya 1995, Vaidya 1996, Bertsimas and Vempala 2004) and references therein) for minimizing \( a_0^T x \) for \( x \in C \), where \( a_0 \) is a vector of \( \mathbb{R}^k \). The algorithm takes as input \( r, R, a_0 \), a real number \( \epsilon \in (0, 1) \), and a separation oracle for \( C \). It outputs a vector \( y \in C \) such that \( a_0^T y \leq a_0^T x + \epsilon \) for any \( x \in C \). The algorithm makes \( N \) iterations and uses the following steps:

1. Let \( \mathcal{R}_0 \subseteq \mathbb{R}^k \) be a bounded region that contains \( B(0, R) \).
2. For \( i = 1 \) to \( N \), choose a point \( y_i \in \mathcal{R}_{i-1} \). Query the separation oracle for \( C \) on \( y_i \). If the oracle returns a "Yes", let \( a_i = -a_0 \). We say in this case that \( i \) is a feasible index. Otherwise, let \( a_i \) be the vector returned by the oracle. In both cases, let \( \mathcal{R}_i \) be a region such that
   \[
   \mathcal{R}_i \supseteq \mathcal{R}_{i-1} \cap \{ x \in \mathbb{R}^k : a_i^T y_i \leq a_i^T x \}. \tag{3.6}
   \]
3. Output \( y_j \), where \( j \) is a feasible index such that \( a_0^T y_j \leq a_0^T y_i \) for all feasible indices \( i \), \( 1 \leq i \leq N \).

The choice of \( y_i \) and \( \mathcal{R}_i \) depends on the specific cutting plane algorithm. In a basic analytic center cutting plane algorithm (see (Atkinson and Vaidya 1995) and references therein, and (Boyd, Vandenberghe and Slif 2008) for a detailed description, which largely inspired our numerical implementation), \( \mathcal{R}_0 \) is the set of vectors \( x \) with \( \|x\|_\infty \leq R \), \( \mathcal{R}_i \) is the RHS of (3.6) for \( i \geq 1 \), and \( y_i \) is the analytic center of \( \mathcal{R}_{i-1} \). Let

\[ I = \{ i \in [1, N] : a_i \neq -a_0 \}, \]

\[ \tilde{C} = \{ x \in \mathcal{R}_0 : a_i^T y_i \leq a_i^T x \text{ for } i \in I \}. \]

Note that \( C \subseteq \tilde{C} \) since \( C \subseteq \mathcal{R}_0 \) and, for \( i \in I \), \( a_i \) is the vector returned by the separation oracle for \( C \) on input \( y_i \) and so, for \( x \in C \), \( a_i^T y_i \leq a_i^T x \). A cutting plane algorithm based on the volumetric center yields the following result.

**Theorem 3.1. (Vaidya 1996, Sections 2 and 4).** Assume \( r \leq 1 \leq \|a_0\| \) and \( R \geq 1 \). There is a cutting plane algorithm that finds a vector \( y \in C \) such that \( a_0^T y \leq a_0^T x + \epsilon \) for every \( x \in \tilde{C} \). The algorithm makes \( N \) calls to the separation oracle for \( C \), where

\[ N = O(k \ln \left( \frac{2kR^2\|a_0\|}{\epsilon r} \right)), \tag{3.7} \]

and runs in \( O(N(k^3 + T)) \) time, where \( T \) is the running time of the oracle.

Since \( C \subseteq \tilde{C} \), \( a_0^T y \leq a_0^T x + \epsilon \) for every \( x \in C \). In the convex program (3.3), \( a_0 = (\pi, 1) \), the number of variables is \( k = l + 1 \), \( C = C' \), and, by Lemma 3.1, \( r = \delta(1 + \|\pi\|)^{-1} \) and \( R = R_1 \). The separation oracle for \( C' \) described in Proposition 3.1 can be used in Step 2 of the cutting plane algorithm.

3.5 A lower bound on \( \pi_{\text{sup}} \) via risk-neutral probabilities

Assume we use a generic cutting plane algorithm with \( N \) iterations to solve the convex program (3.3). For any \( P \in \mathbb{P} \) such that \( E_P(\phi) = \pi \), it follows from (2.5) and (3.2) that \( E_P(\psi) \leq \pi_{\text{sup}} \). We calculate below a lower bound on \( \pi_{\text{sup}} \) by choosing \( P \) to be a weighted
average of the risk-neutral probabilities defined in Assumption A2 or generated by the cutting plane algorithm. For \( i \in I \), \( a_i \) is the vector returned by the separation oracle for \( V' \) on input \( y_i = (\beta_i, \gamma_i) \) and so, by Proposition 3.1, there is \( P_i \in \mathbb{P} \) such that

\[
a_i = (E_{P_i}(\phi), 1) \text{ and } a'_i \leq E_{P_i}(\psi),
\]

(3.8)

where \( a'_i = a_i^T y_i \). For \( 1 \leq i \leq l \), set \( a_{i+N} = (\pi + \delta \epsilon_i, 1) \) and \( a_{i+N+1} = (\pi - \delta \epsilon_i, 1) \). Finally, for \( N + 1 \leq i \leq N + 2l \), set \( a'_i = -q \), and let \( I' = I \cup [N + 1, N + 2l] \). By Assumption A2, for \( N + 1 \leq i \leq N + 2l \), there is \( P_i \in \mathbb{P} \) such that (3.8) holds. Let \( a_0 = (\pi, 1) \) and consider the linear program:

\[
b_0 = \max_{\lambda} \sum_{i \in I'} \lambda_i a'_i
\]

subject to:

\[
\lambda_i \geq 0 \text{ for } i \in I', \text{ and } \sum_{i \in I'} \lambda_i a_i = a_0.
\]

(3.10)

This program has \( |I'| + l + 1 \) constraints and \( |I'| \) variables, with \( |I'| \leq N + 2l \). It is feasible since the constraints (3.10) are satisfied when \( \lambda_i = 0 \) for \( i \in I \) and \( \lambda_i = (2l)^{-1} \) for \( i \in [N + 1, N + 2l] \). By (3.8), for any \( \lambda_i \)’s satisfying (3.10), \( \sum_{i \in I'} \lambda_i P_i(\psi) = \pi \) and \( \sum_{i \in I'} \lambda_i a'_i \leq \sum_{i \in I'} \lambda_i E_{P_i}(\psi) \). Thus \( P = \sum_{i \in I'} \lambda_i P_i \) is a risk-neutral probability, \( E_P(\phi) = \pi \) and \( \sum_{i \in I'} \lambda_i a_i' \leq E_P(\psi) \). Hence \( b_0 \leq E_P(\psi) \leq \pi_{\text{sup}} \). The following lemma will show the tightness of this lower bound on \( \pi_{\text{sup}} \).

**Lemma 3.2.** For any generic cutting plane algorithm, \( \inf_{x \in C} a_0^T x \leq b_0 \).

Combining the preceding results yields the following.

**Theorem 3.2.** Under Assumptions A1, A2 and A3, \( V' \) admits a separation oracle that runs in \( T + O(1) \) time, where \( T \) is the running time of the subroutine in Assumption A3, and \( V' \subseteq B(0, R_1) \). By solving the convex program (3.3), we can calculate in \( O(N(l^3 + T)) \) time a vector \( (\beta^*, \gamma^*) \in V' \) such that \( ||\beta^*||_\infty \leq R_0 \) and

\[
\pi_{\text{sup}} \leq \beta^*^T \pi + \gamma^* \leq \pi_{\text{sup}} + \epsilon,
\]

(3.11)

where

\[
N = O(l \ln \frac{l(1 + q)(1 + ||\pi||)}{\epsilon \delta}).
\]

(3.12)

In addition, by solving a linear program with \( O(N) \) variables and constraints, we can find weights \( \lambda_i \geq 0, i \in I' \), that sum up to 1, with \( E_P(\phi) = \pi \), where \( P = \sum_{i \in I'} \lambda_i P_i \) is a risk-neutral probability, and

\[
\beta^*^T \pi + \gamma^* \leq E_P(\psi) + \epsilon.
\]

(3.13)

Thus the algorithm calculates \( \pi_{\text{sup}} \) with precision \( \epsilon \) and outputs a portfolio that super-replicates \( \psi \) at cost at most \( \pi_{\text{sup}} + 2\epsilon \).

**Proof.** As shown in Subsection 3.4, we can solve the convex program (3.3) by using the cutting plane algorithm in (Vaidya 1996, Sections 2 and 4). The algorithms finds \( y = (\beta^*, \gamma^*) \in V' \) such that (3.11) holds. Since \( r = \delta(1 + ||\pi||)^{-1} \) and \( R = R_1 \), (3.12) follows from (3.7) after some calculations. Furthermore, since \( (\beta^*, \gamma^*) \in V \), the discussion in subsection 2.3 shows that \( \psi \) is super-replicated by the portfolio \( \beta^*^T \phi + \gamma^* + \epsilon \), whose cost \( \beta^*^T \pi + \gamma^* + \epsilon \) is at most \( \pi_{\text{sup}} + 2\epsilon \). Lemma 3.1 implies that \( ||\beta^*||_\infty \leq R_0 \). On the other hand, by Lemma 3.2, if we solve the linear program (3.9) and (3.10), we find \( b_0 \) such that \( \inf_{x \in \tilde{C}} a_0^T x \leq b_0 \leq E_P(\psi) \), where \( P \) is a risk-neutral probability such that \( E_P(\phi) = \pi \). Since, by Theorem 3.1, \( a_0^T y \leq a_0^T x + \epsilon \) for \( x \in \tilde{C} \), \( a_0^T y \leq E_P(\psi) + \epsilon \). Hence (3.13).
4 Recursive calculation of the super-hedging cost

Theorem 3.2 shows how to calculate \( \pi_{\text{sup}} \) if Assumptions A1, A2 and A3 hold. We will see in Section 5 how to verify Assumptions A1 and A2. We show in this section that A3 holds for a class of financial derivatives when the state-space is finite and under a geometric condition described in Assumption A4. We also give a construction of the subroutine needed in A3 by describing an algorithm that calculates the super-hedging cost of a financial derivative \( \Psi \) by backward induction using concave envelopes, in the same spirit as in (Carassus, Gobet and Temam 2007), and applying the algorithm with \( \Psi = \psi - \beta^T \phi \), for a given vector \( \beta \).

Let \( f \) be a real-valued function defined on a subset \( W \) of \( \mathbb{R}^d \) and bounded above by a linear function. Denote by \( \tilde{W} \) the convex hull of \( W \) and by \( \tilde{f} \) the concave envelope of \( f \), i.e. the smallest concave function on \( \tilde{W} \) bounded below by \( f \) on \( W \). If \( x \in \tilde{W} \), denote by \( \tilde{Q}(x,W) \) the set of non-negative functions \( \tilde{Q} \) on \( W \) that take positive values on a finite number of elements, sum up to 1, with \( \sum_{y \in W} \tilde{Q}(y)y = x \). Note that \( \tilde{Q} \) defines a probability on \( W \), endowed with its Borel \( \sigma \)-algebra. It can be shown (Boyd and Vandenberghge 2004, Exercise 3.30) that, for \( x \in \tilde{W} \),

\[
\tilde{f}(x) = \sup_{\tilde{Q} \in \tilde{Q}(x,W)} E_{\tilde{Q}}(f), \tag{4.1}
\]

where

\[
E_{\tilde{Q}}(f) = \sum_{y \in W} \tilde{Q}(y)f(y).
\]

When \( W \) is finite, (4.1) can be rewritten as

\[
\tilde{f}(x) = \sup \left\{ \sum_{y \in W} \tilde{Q}(y)f(y) | \tilde{Q}(y) \geq 0 \text{ for } y \in W, \sum_{y \in W} \tilde{Q}(y) = 1, \sum_{y \in W} \tilde{Q}(y)y = x \right\}, \tag{4.2}
\]

where \( \tilde{Q} \) is a real-valued function on \( W \). By linear programming duality,

\[
\tilde{f}(x) = \min_{\eta_0 \in \mathbb{R}, \eta \in \mathbb{R}^d} \left\{ \eta_0 + \eta^T x | f(y) \leq \eta_0 + \eta^T y \text{ for } y \in W \right\}. \tag{4.3}
\]

Let \( (\eta_0, \eta) \) be a pair that attains the RHS of (4.3). Then, for \( y \in W \),

\[
f(y) \leq \tilde{f}(x) + \eta^T (y - x). \tag{4.4}
\]

Thus, \( f \) is upper-bounded by a linear function valued at \( \tilde{f}(x) \) at \( x \).

For \( 1 \leq i \leq m \), let \( D_i = \text{Im}(X_1, \ldots, X_i) \) be the set of paths that \( X \) can follow from time-step 1 through \( i \), and set \( D_0 = \{ \emptyset \} \). For \( \theta \in D_i \), let

\[
D(\theta) = \{ x \in \mathbb{R}^d : (\theta, x) \in D_{i+1} \} \tag{4.5}
\]

be the set of possible values of \( X_{i+1} \) given that \( X \) has followed the path \( \theta \) in the first \( i \) time-steps. By convention, if \( i = 0 \) and \( \theta = \emptyset \), \( (\theta, x) \) refers to \( x \). If \( \zeta \) is a real-valued function on \( D_{i+1} \), denote by \( \zeta(\theta, \cdot) \) the function that maps \( x \) to \( \zeta(\theta, x) \) for \( x \in D(\theta) \). The rest of this section makes the following assumption. By convention, \( x_0 = X_0 \).

A4. \( \Omega \) is finite and, if \( 0 \leq i \leq m - 1 \) and \( \theta = (x_1, \ldots, x_i) \in D_i \), then \( x_i \in \overline{D(\theta)} \).

Assumption A4 implies that, for any given path that \( X \) has followed in the first \( i \) time-steps, \( X_i \) belongs to the convex hull of the set of possible values of \( X_{i+1} \). Consider now a financial derivative \( \Psi \) of the form \( \Psi = \Psi^*(X_1, \ldots, X_m) \), where \( \Psi^* \) is a real-valued function defined on \( D_m \) that can be calculated in finite time. When \( m = 1 \), Proposition 4.1 shows that,

\[
c(\Psi) = \Psi^*(X_0) = \sup_{\tilde{Q} \in \tilde{Q}(X_0,D_1)} E_{\tilde{Q}}(\Psi^*),
\]

and so \( c(\Psi) \) is equal to the concave envelope of \( \Psi^* \) evaluated at \( X_0 \). Proposition 4.1 also shows how to calculate by backward induction the super-hedging cost of \( \Psi \) in an \( m \)-period market, for any integer \( m \).
Proposition 4.1. Define the functions $\Psi_i^*$ by backward induction as follows: $\Psi_i^* = \Psi^*$ and $\Psi_i^*(\theta) = \Psi_{i+1}^*(\theta, x_i)$ for $0 \leq i \leq m - 1$ and $\theta = (x_1, \ldots, x_i) \in D_i$. Let $\Psi_i$ be the financial derivative $\Psi_i^*(X_1, \ldots, X_i)$. Then $c(\Psi) = \Psi_0$ and

$$
\Psi_i^*(\theta) = \sup_{\mathbb{Q} \in \mathbb{Q}(x_i, D(\theta))} E_{\mathbb{Q}}(\Psi_{i+1}^*(\theta, )). 
$$

We can interpret $\Psi_i$ as the super-hedging cost at time-step $i$ of $\Psi$, and (4.6) as saying that $\Psi_i$ is equal to the super-hedging cost of $\Psi_{i+1}$ in the underlying single-period market at time-step $i$.

Proposition 4.2. For $\theta = (x_1, \ldots, x_i) \in D_i$, choose a probability $\mathcal{P}(\theta) \in \mathbb{Q}(x_i, D(\theta))$. There is a risk-neutral probability $\mathcal{P}$ such that, for any deterministic function $\eta^*$ on $D_m$, $E_{\mathcal{P}}(\eta^*) = \eta^*_0(\emptyset)$, where $\eta = \eta^*(X_1, \ldots, X_m)$, and the functions $\eta_i^*$ are defined on $D_i$ by backward induction as follows: $\eta_m^* = \eta^*$ and, for $0 \leq i \leq m - 1$ and $\theta \in D_i$,

$$
\eta_i^*(\theta) = E_{\mathcal{P}(\theta)}(\eta_{i+1}^*(\theta,.)).
$$

Furthermore, $c(\Psi) = E_{\mathcal{P}}(\Psi)$ if all $\mathcal{P}(\theta)$ attain the RHS of (4.6).

We now use Propositions 4.1 and 4.2 to show that Assumption A3 holds and to give a generic construction of the subroutine needed in Assumption A3. Assume that $\psi = \psi^*(X_1, \ldots, X_m)$ and $\phi = \phi^*(X_1, \ldots, X_m)$, where $\psi^*$ (resp. $\phi^*$) is a function from $D_m$ to $\mathbb{R}$ (resp. $\mathbb{R}'$). On input $\beta$, the subroutine uses the following steps.

1. Let $\Psi = \psi - \beta^T \phi$, $\Psi_m^* = \psi^* - \beta^T \phi^*$ and $\phi_m^* = \phi^*$.

2. For $i = m - 1$ down to 0 and $\theta = (x_1, \ldots, x_i) \in D_i$, choose a probability $\mathcal{P}(\theta) \in \mathbb{Q}(x_i, D(\theta))$ that maximizes $E_{\mathcal{P}(\theta)}(\Psi_i^*(\theta,.))$. Set $\Psi_i^*(\theta) = E_{\mathcal{P}(\theta)}(\Psi_{i+1}^*(\theta,.))$ and $\phi_i^*(\theta) = E_{\mathcal{P}(\theta)}(\phi_{i+1}^*(\theta,.))$.

3. Output $c(\Psi) = \Psi_i^*(\emptyset)$ and $E_{\mathcal{P}}(\phi) = \phi_0^*(\emptyset)$, where $\mathcal{P} \in \mathcal{P}$ is obtained by pasting the probabilities $\mathcal{P}(\theta)$.

In other words, we find by backward induction, in every single-period market at time-step $i$, a probability $\mathcal{P}(\theta)$ that attains RHS of (4.6), and use the probabilities $\mathcal{P}(\theta)$ to calculate both $c(\Psi)$ and $E_{\mathcal{P}}(\phi)$. By Proposition 4.2, $c(\Psi) = E_{\mathcal{P}}(\Psi)$.

Finding $\mathcal{P}(\theta)$ can be done in finite time, as shown in Subsection 4.1, and so Assumption A3 holds. But, since $|D_{m-1}|$ is in general exponential in $m$, so is the running time of a naive implementation of Step 2. The running time can often be considerably reduced using Remarks 4.1 and 4.2 below and techniques used in the valuation of path-dependent derivatives via binomial trees (Hull 2012, Section 26.5). The optimized subroutine replaces the loop on $\theta$ in Step 2 by a loop on $x_i$ and on at most one additional state variable. For instance, if $\psi$ is a variance swap and $\phi$ consists of call options, the loop on $\theta$ is replaced by a loop on $x_i$. If $\psi$ is a volatility swap (resp. Asian option), we can replace the loop on $\theta$ by a loop on $x_i$ and on the current realized variance (resp. the price running sum). See Section 5 for details.

Remark 4.1. Fix $i \in \{0, \ldots, m\}$. Consider a financial derivative $\zeta$ which is a deterministic function of $X_0, \ldots, X_m$, and a financial derivative $\zeta'$ which is a deterministic function of $X_0, \ldots, X_i$. Let $\Psi = \zeta + \zeta'$. It can be shown by backward induction that $\Psi_i = \zeta_i + \zeta'_i$, where $\Psi_i$ (resp. $\zeta_i$) is the super-hedging cost of $\Psi$ (resp. $\zeta$) at time-step $i$. 

10
Remark 4.2. Fix \(i \in \{1, \ldots, m - 1\}\). Consider a financial derivative \(\zeta\) of the form \(\zeta = \zeta^*(X_1, \ldots, X_m)\), where \(\zeta^*\) is a real-valued function on \(D_m\). Assume that \(\zeta^*(x_1, \ldots, x_m)\) and \(D(x_1, \ldots, x_j)\) depend on \((x_1, \ldots, x_i)\) only through a (one or multi-dimensional) deterministic function \(h(x_1, \ldots, x_i)\) for \(j \geq i\). It can be shown by backward induction that the super-hedging cost \(\zeta_i\) of \(\zeta\) at time-step \(i\) is a deterministic function of \(X_i\) and of \(h(X_1, \ldots, X_i)\).

4.1 Convex hull calculation

By (4.2) thru (4.4), we can use linear programming to find \(Q \in \mathbb{Q}(x_i, D(\theta))\) that attains the RHS of (4.6), where \(\theta = (x_1, \ldots, x_i) \in D_i\). When \(d = 1\), this can be done more efficiently via the following proposition.

Proposition 4.3 ((Andrew 1979)). Given a finite set \(W \subseteq \mathbb{R}\) whose elements \(x_1, \ldots, x_n\) are sorted in increasing order, a real number \(x \in [x_1, x_n]\), and a function \(f\) that takes known values on \(W\), we can calculate in \(O(n)\) time a probability \(Q \in \mathbb{Q}(x, W)\) that maximizes \(E_Q(f)\), and a real number \(\xi^*\) such that, for \(y \in W\),

\[
f(y) \leq E_Q(f) + \xi^*(y - x).
\]

Furthermore, \(Q\) is supported on two points.

The algorithm, due to (Andrew 1979), first calculates the ordered subset \(U(j)\) of \(W\), \(2 \leq j \leq n\), recursively as follows. Let \(U(2) = \{x_1, x_2\}\). Assume \(U(j - 1) = \{x_{1}', \ldots, x_{k}'\}\). Let \(k\) be the largest index such that \((x_{k}', f(x_{k}'))\) is above the segment \([(x_{k-1}', f(x_{k-1}')), (x_j, f(x_j))]\), if such an index exists, otherwise set \(k = 1\). Then \(U(j) = \{x_{1}', \ldots, x_k', x_j\}\). Let \(x'\) and \(x''\) be consecutive elements of \(U(n)\) such that \(x \in [x', x'']\). The algorithm outputs the probability \(Q\) that assigns \(s = (x'' - x)/(x'' - x')\) to \(x'\) and \(1 - s\) to \(x''\),

\[
\xi^* = \frac{f(x'') - f(x')}{x'' - x'}.
\]

5 Examples

Let \(S\) be a stock valued at \(S_i\) at time-step \(i\), \(0 \leq i \leq m\), where \(S_0\) is known. For \(1 \leq i \leq m\), we are given a (possibly empty) increasing sequence \(K_{i,j}\) of positive strikes, \(1 \leq j \leq l_i\), together with prices \(c_{i,j}\) of calls with maturity \(t_i\) and strike \(K_{i,j}\). By convention, \(l_i = 0\) if no calls trade at time-step \(i\). Let \(K\) be the set that consists of \(S_0\) and of \(K_{i,j}\), \(1 \leq i \leq m\), \(1 \leq j \leq l_i\). Given subsets \(F_i \supseteq K\) of \(\mathbb{R}^+\) for \(1 \leq i \leq m\), consider the market \(\mathcal{M}(F_1, \ldots, F_m)\) where \(S_i\) ranges in \(F_i\) for \(1 \leq i \leq m\). We formally build \(\mathcal{M}(F_1, \ldots, F_m)\) by setting \(\Omega = \{S_0\} \times F_1 \times \cdots \times F_m\), with \(S_i(\omega) = x_i\) for \(\omega = (x_0, \ldots, x_m) \in \Omega\) and \(0 \leq i \leq m\). We assume that \(F_{i-1} \subseteq F_i\) for \(2 \leq i \leq m\), so that Assumption A4 holds if the sets \(F_i\), \(1 \leq i \leq m\), are finite. If \(F_i = F\) for \(1 \leq i \leq m\), denote \(\mathcal{M}(F_1, \ldots, F_m)\) by \(\mathcal{M}_m(F)\).

Definition 5.1. Consider an ordered pair \(\{k_s, k^*\}\) of fictitious strikes such that

\[0 \leq k_s < \min(K) \leq \max(K) < k^* \leq \infty.\]

For \(1 \leq i \leq m\), set

\[K_{i,0} = k_s, K_{i,l_i+1} = k^*, c_{i,0} = S_0 - k_s \text{ and } c_{i,l_i+1} = 0.\]

We say that \(\{k_s, k^*\}\) is acceptable if, for \(1 \leq i \leq i' \leq m\), \(i \leq i'' \leq m\), \(1 \leq j \leq l_i\), \(0 \leq j' \leq l_{i'} + 1\), \(0 \leq j'' \leq l_{i''} + 1\), if \(K_{i',j'} \leq K_{i,j} \leq K_{i',j''}, (i, j) \notin \{(i', j'), (i'', j'')\}\), and \(K_{i',j''} < K_{i''',j'''}\), then

\[
\max(0, S_0 - K_{i,j}) < c_{i,j} < wc_{i',j'} + (1 - w)c_{i'',j''},
\]

where \(w = (K_{i'',j''} - K_{i,j})/(K_{i'',j''} - K_{i',j'})\). By convention, \(w = 1\) if \(K_{i'',j''} = \infty\).
Proposition 5.1. Assume that an acceptable pair \( \{k_s, k^*\} \) is contained in \( F_i \), for \( 1 \leq i \leq m \). Let \( \delta_0 = \delta_0(k_s, k^*) \) be the minimum of \( 1/2 \) and of the minimum difference between the right-hand sides and left-hand sides of the inequalities in (5.2). Then A1 and A2 hold in the market \( \mathcal{M} = \mathcal{M}(F_1, \ldots, F_m) \) if \( q \geq \max(c(\psi; \mathcal{M}), c(\psi; \mathcal{M})) + \delta_0 \sqrt{I} S_0 \) and \( 0 < \delta < \delta_0 \). Furthermore, \[
\|\pi\| \leq S_0 \sqrt{I}. \tag{5.3}
\]

In the following examples, we show that A3 holds as well. We then use Theorem 3.2 to calculate an optimal super-replicating price and a corresponding hedging portfolio for \( \psi \) via the call components of \( \phi \). An optimal sub-replicating price and a corresponding hedging portfolio can be derived as well using Remark 2.1. In our examples, we first derive discretized optimal model-independent bounds by assuming the \( F_i \)’s to be finite, then give an empirical and a theoretical estimate of the discretization error. The empirical estimate is calculated using a large number of discretization points. Our numerical examples were obtained using an analytic center cutting plane algorithm with at most 200 iterations that calculated the model-independent price bound (or its discrete approximation) within an error of order \( 10^{-5} \). The simulation experiments were performed on a desktop PC with an Intel Pentium 2.90 GHz processor and 4 Go of RAM, running Windows 7 Professional. The codes were written in the C++ programming language, and the compiler used was Microsoft Visual C++ 2013. The computing time is given in seconds.

5.1 Forward start options

Consider a forward start option \( \psi \). For ease of exposition, assume the option is an at the money call that pays \( \max(0, S_2 - S_1) \) at maturity. Extension to the general case is straightforward. The derivative \( \Psi \) pays \( \Psi^*(S_1, S_2) \), where
\[
\Psi^*(x_1, x_2) = \max(0, x_2 - x_1) - b_1^T f_1(x_1) - b_2^T f_2(x_2).
\]
For \( x_1 \in F_1 \), let
\[
\Psi^*_1(x_1; F_2) = \sup_{Q \in Q(x_1, F_2)} E_Q(\Psi^*(x_1, \cdot)). \tag{5.4}
\]
If \( F_1 \) and \( F_2 \) are finite, by Proposition 4.1, in the market \( \mathcal{M}(F_1, F_2) \), the super-hedging cost of \( \Psi \) at time-step 1 is \( \Psi^*_1(S_1; F_2) \), and the super-hedging cost of \( \Psi \) at time-step 0 is
\[
c(\Psi; \mathcal{M}(F_1, F_2)) = \sup_{Q' \in Q(S_0, F_1)} E_{Q'}(\Psi^*_1(S_1; F_2)). \tag{5.5}
\]
We illustrate the calculation of \( c(\Psi; \mathcal{M}_2(F)) \) when \( S_0 = 100 \) and \( F = \{70, 80, \ldots, 130\} \). Assume \( \phi \) consists of the calls maturing at time-step \( i \) with strike \( K_{i,j} = 80 + 10j \) for \( 1 \leq i \leq 2 \) and \( 1 \leq j \leq 3 \). Let \( b_1 = (-0.3, -0.2, -0.4) \) and \( b_2 = (0.5, 0.4, 0.3) \). Proposition 4.3 shows how to calculate \( \Psi^*_1(x_1; F) \) for \( x_1 \in F \) and probabilities \( P(x_1) \) and \( P(\emptyset) \) that attain the RHS of (5.4) and (5.5), respectively. Using Proposition 4.2, we can then calculate \( E_P(\phi) \), where \( P \)
is a risk-neutral probability such that $c(\Psi; \mathcal{M}_2(F)) = E_P(\Psi)$. Table 1 lists the values of $\Psi$ when $S_1 = 90$. Fig. 1 plots the function $\Psi^*(90,.)$ and its concave envelope, which shows that $\Psi^*_1(90; F_1) = 2/3 \times 5 + 1/3 \times 0 = 10/3$. The probability that assigns a weight $2/3$ to 100 and $1/3$ to 70 maximises the RHS of (5.4) when $x_1 = 90$. We can perform a similar calculation for each $x_1 \in F$ and then calculate $c(\Psi; \mathcal{M}_2(F))$ via (5.5). Fig. 2 draws a tree by connecting each $x_1 \in F$ (resp. $S_0$) to the support of $\mathcal{P}(x_1)$ (resp. $\mathcal{P}(\emptyset)$), and Table 2 gives the probability $p_n$ assigned to the largest element in the support of $\mathcal{P}(x_1)$ (resp. $\mathcal{P}(\emptyset)$). It also shows that $E_P(\eta) = 7.5$, where $\eta$ is the ATM vanilla call maturing at the second time-step. The expected value under $P$ of any component of $\phi$ can be calculated in a similar manner.

We now show how to calculate the best super-replicating (resp. sub-replicating) price $\pi_{\text{sup}}(\mathbb{R}^+)$ (resp. $\pi_{\text{inf}}(\mathbb{R}^+)$) of $\psi$ without restrictions on $S_1$ and $S_2$ other than being non-negative, and set $\Psi^*_1(x_1) = \Psi^*_1(x_1; \mathbb{R}^+)$ for $x_1 \geq 0$. It follows from (5.4) and the convexity of $\Psi^*_1(x_1,.)$ on any interval disjoint with $\mathcal{K}$ that $\Psi^*_1(x_1)$ depends only on the values of $\Psi^*_1(x_1,.)$ on $\mathcal{K} \cup \{0\}$ and on its asymptotic slope on $[\max(\mathcal{K}), \infty)$. Furthermore, it can be shown that $\Psi^*_1$ is linear on $[\max(\mathcal{K}), \infty)$, and so we only need to know the values of $\Psi^*_1$ on $[0, \max(\mathcal{K})]$ and its slope on $[\max(\mathcal{K}), \infty)$ to calculate $c(\Psi; \mathcal{M}_2(\mathbb{R}^+))$ via (5.5). This suggests that $\pi_{\text{sup}}(\mathbb{R}^+)$ is well approximated by the best super-replicating price $\pi_{\text{sup}}(F_1, F_2)$ of $\psi$ in the market $\mathcal{M}(F_1, F_2)$, where

$$F_1 = \mathcal{K} \cup \{\max(\mathcal{K})/n \leq j \leq n\} \cup \{\epsilon^{-1} \max(\mathcal{K})\}, \text{ and} \quad (5.6)$$

$$F_2 = \mathcal{K} \cup \{0, \epsilon^{-1} \max(\mathcal{K}), \epsilon^{-2} \max(\mathcal{K})\}, \quad (5.7)$$

$n$ is a positive integer, and $\epsilon \in (0, 1)$. Theorem 5.1 below shows how to calculate $\pi_{\text{sup}}(F_1, F_2)$ and gives an upper bound on the discretization error. The constants behind the $O$ notation in (5.8) and in Section F depend on $l$, $S_0$, $k_0$, the calls strikes, maturities and prices, but do not depend on $n$ and $\epsilon$.

**Theorem 5.1.** Assume that $\{0, k_0^*\}$ is acceptable, where $k_0^*$ is a positive real number. Then, for $\epsilon \in (0, \max(\mathcal{K})/k_0^*)$, $\pi_{\text{sup}}(F_1, F_2)$ can be calculated in $O(N(l^3 + \ln))$ total time with precision $\epsilon$ via the convex program (3.3), where

$$N = O(l \ln (\frac{l(1 + S_0)}{\epsilon \delta_0(0, k_0^*)})).$$

$V'$ has a separation oracle that runs in $O(\ln)$ time. Furthermore,

$$\pi_{\text{sup}}(F_1, F_2) - \pi_{\text{sup}}(\mathbb{R}^+) = O(n^{-2} + \epsilon'). \quad (5.8)$$

**Proof.** Let $\epsilon' \in (0, \max(\mathcal{K})/k_0^*)$ and $k^* = \epsilon^{-1} \max(\mathcal{K})$. Since $k^* \geq k_0^*$, it follows from Definition 5.1 that $\{0, k^*\}$ is acceptable. Furthermore, an easy calculation shows that $\delta_0(0, k^*) \geq \delta_0(0, k_0^*)$. On the other hand, since $-\psi \leq 0$ and $\psi \leq S_2$, the super-hedging costs of $\psi$ and of $-\psi$ in the market $\mathcal{M}(F_1, F_2)$ are at most $S_0$. Thus, by Proposition 5.1, Assumptions A1 and A2 hold for $\mathcal{M}(F_1, F_2)$ if

$$q = S_0(1 + \sqrt{l}) \text{ and } \delta = \delta_0(0, k_0^*)/2. \quad (5.9)$$

Proposition 4.3 shows how to calculate $\Psi_1^*(x_1; F_2)$ for all $x_1 \in F_1$, $c(\Psi; \mathcal{M}(F_1, F_2))$, and probabilities $\mathcal{P}(x_1)$ and $\mathcal{P}(\emptyset)$ that attain the right-hand sides of (5.4) and (5.5), respectively, in total time $O(|F_1||F_2|)$. By Proposition 4.2, there is a risk-neutral probability $P$ in $\mathcal{M}(F_1, F_2)$ such that $c(\Psi; \mathcal{M}(F_1, F_2)) = E_P(\Psi)$ and, for any financial derivative $\eta = \eta^*(S_1, S_2)$, if we set $\eta_1^*(x_1) = E_{P(\cdot)}(\eta^*(x_1,.))$ for $x_1 \in F_1$, then $E_{P(\emptyset)}(\eta_1^*) = E_{P}(\eta)$. Thus, we can then calculate $E_{P}(\phi)$ in $O(l)$ time, and so A3 holds, with $T = O(\ln)$. The first part of the theorem then follows from Theorem 3.2 and (5.3). The proof of (5.8) is in Section F.

</tr>
</tbody>
</table>

Figure 1: The solid line plots the payoff of $\Psi$ when $S_1 = 90$ and the dotted line plots the corresponding upper hull.

It follows from Theorem 5.1 that, as $\epsilon$ goes to 0, we can calculate $\pi_{\text{sup}}(\mathbb{R}^+)$ with precision $O(\epsilon)$ in total time $O(\epsilon^{-1/2} \ln(\epsilon^{-1}))$ by setting $n = \epsilon^{-1/2}$ and $\epsilon' = \epsilon$. (Beiglböck, Henry-Labordère and Penkner 2013) calculate a discrete approximation of $\pi_{\text{sup}}(\mathbb{R}^+)$ similar to $\pi_{\text{sup}}(F_1, F_2)$ using linear programming with $\Theta(n)$ variables and constraints. Our algorithm is much faster for large values of $n$.

We calculate $\pi_{\text{inf}}(\mathbb{R}^+)$ in a similar manner using Remark 2.1 and setting

$$\Psi^*(x_1, x_2) = -\max(0, x_2 - x_1) - b_1^T f_1(x_1) - b_2^T f_2(x_2).$$

We first calculate the best sub-replicating price $\pi_{\text{inf}}(F'_1, F'_2)$ of $\psi$ in the market $\mathcal{M}(F'_1, F'_2)$, where

$$F'_1 = \{0, \epsilon'^{-1} (\max \mathcal{K})\} \cup \mathcal{K},$$

$$F'_2 = F'_1 \cup \{\epsilon'^{-2} (\max \mathcal{K})\},$$

and $0 < \epsilon' < 1$. The choice of $F'_1$ can be motivated in a way similar to that of $F_1$ in (5.6) and (5.7), by noting that $\Psi^*(x_1,.)$ is linear on any interval disjoint with $\mathcal{K} \cup \{x_1\}$, and that $\Psi^*_1$ is convex on any interval disjoint with $\mathcal{K}$. The constant behind the $O$ notation in (5.10) depends on $l$, $S_0$, the calls strikes, maturities and prices, but does not depend on $\epsilon'$.

**Theorem 5.2.** Assume that $\{0, k_0^*\}$ is acceptable, where $k_0^*$ is a positive real number. Then, for $\epsilon' \in (0, \max(\mathcal{K})/k_0^*)$, $\pi_{\text{inf}}(F'_1, F'_2)$ can be calculated in $O(Nl^3)$ total time with precision $\epsilon$ via the convex program (3.3), where

$$N = O(l \ln(l(1 + S_0)/\epsilon k_0^*)).$$

$V'$ has a separation oracle that runs in $O(l^2)$ time. Furthermore,

$$\pi_{\text{inf}}(\mathbb{R}^+) - \pi_{\text{inf}}(F'_1, F'_2) = O(\epsilon').$$

(5.10)

**Proof.** The first part of the theorem can be shown as in the proof of Theorem 5.1. The proof of (5.10) is in Section G.

\[\square\]
Figure 2: Connecting each $x_1 \in F$ (resp. $S_0$) to the support of a probability that maximises the RHS of (5.4) (resp. (5.5)). For instance, the probability that assigns a weight $2/3$ to 100 (represented by L) and $1/3$ to 70 (represented by O) maximises the RHS of (5.4) when $x_1 = 90$ (represented by F).

In our numerical example, \( t_1 = 1/6 \) (two months) and \( t_2 = 5/12 \) (five months), where \( t_i \) is the maturity of time-step \( i \), and the market price \( c_{i,j} \) of the call maturing at time-step \( i \) with strike \( K_{i,j} = 60 + 10j \) is equal to the Black-and-Scholes price with the corresponding strike, maturity \( t_i \) and volatility \( \sigma = 0.2 \) for \( 1 \leq i \leq 2 \) and \( 1 \leq j \leq 7 \). We have checked numerically that \( \{0, \epsilon'^{-1}(\max K)\} \) is acceptable. Table 3 gives the optimal super-replicating price and the amount of call positions in an optimal super-replicating portfolio. Table 4 gives the discretization error and computing time as a function of \( n \).

5.2 Variance swaps

Consider a variance swap that pays at maturity \( T \) the amount

\[
\psi = \sum_{i=1}^{m} H(S_{i-1}, S_i),
\]

where \( H \) is a deterministic bivariate function. For instance, \( H(x, y) = T^{-1} \ln^2(y/x) \) for standard variance swaps, \( H(x, y) = T^{-1} \ln^2(y/x)1_{y \in I} \) for a corridor variance swaps, where \( I \) is a specified interval of \( \mathbb{R}^+ \), and \( H(x, y) = \max(0, y/x - K) \) for a cliquet call, where \( K \) is a constant. In practice, \( m \) is quite large and \( l_i = 0 \) for most values of \( i \). Let \( H_i(x, y) = H(x, y) - b^T_i f_i(y) \), so that

\[
\Psi = \sum_{i=1}^{m} H_i(S_{i-1}, S_i). \tag{5.11}
\]

Let \( \pi_{\text{sup}}(F) \) (resp. \( \pi_{\text{inf}}(F) \)) denote the optimal super-replicating (resp. sub-replicating) price of a standard variance swap \( \psi \) in the market \( M_m(F) \). For standard variance swaps, \( F \) must be bounded away from 0 in order for the best super-replicating price to be finite. Consider now an interval \([L, M]\) that contains \( \mathcal{K} \), with \( L > 0 \), and let

\[
F_0 = \mathcal{K} \cup \{L(M/L)^{j/n}, j \in \{0, \ldots, n\}\}. \tag{5.12}
\]

Given \( i \in [0, m] \), consider the financial derivative \( \zeta = \sum_{j=i+1}^{m} H_j(S_{j-1}, S_j) \). Let \( \Psi_i \) (resp. \( \zeta_i \)) denote the super-hedging cost of \( \Psi \) (resp. \( \zeta \)) at time-step \( i \) in \( M_m(F_0) \). Since \( \zeta \) does not depend on \( S_0, \ldots, S_{i-1} \), Remark 4.2 shows that \( \zeta_i = c_i(S_i) \), where \( c_i \) is a deterministic function on \( F_0 \),
with $c_m = 0$. Since $\Psi = \zeta + \sum_{j=1}^i H_j(S_{j-1}, S_j)$, Remark 4.1 shows that

$$
\Psi_i = c_i(S_i) + \sum_{j=1}^i H_j(S_{j-1}, S_j),
$$

(5.13)

and so, by (4.6), for $0 \leq i \leq m - 1$,

$$
c_i(S_i) = \sup_{Q \in \mathcal{Q}(S_i, F_0)} E_Q(c_{i+1} + H_{i+1}(S_{i+1}, \cdot)).
$$

(5.14)

We can interpret (5.14) by observing that the super-hedging cost of $\zeta$ at time-step $i + 1$ is $c_{i+1}(S_{i+1}) + H_{i+1}(S_i, S_{i+1})$.

**Theorem 5.3.** Assume that $\{L, M\}$ is acceptable. Let $B = mT^{-1} \ln^2(M/L)$. Then $\pi_{\text{sup}}(F_0)$ and $\pi_{\text{inf}}(F_0)$ can be calculated in $O(N(3 + n^2 m + lmn))$ total time with precision $\epsilon$ via the convex program (3.3), where

$$
N = O(l \ln\left(\frac{l(1 + S_0)(1 + B)}{\epsilon \delta_0(L, M)}\right)),
$$

and $V'$ has a separation oracle that runs in $O(n^2 m + lmn)$ time. Furthermore,

$$
\pi_{\text{sup}}([L, M]) - \pi_{\text{sup}}(F_0) = O\left(\frac{M}{M - L} \ln^3 \left(\frac{M}{L}\right) \frac{m}{Tn^2}\right),
$$

(5.15)

and

$$
\pi_{\text{inf}}([L, M]) - \pi_{\text{inf}}(F_0) = O\left(\ln^2 \left(\frac{M}{L}\right) + \ln^3 \left(\frac{M}{L}\right) \frac{m}{Tn^2}\right).
$$

(5.16)

**Proof.** Since $0 \leq \psi \leq B$, max$(c(\psi; \mathcal{M}_m(F_0)), c(-\psi; \mathcal{M}_m(F_0))) \leq B$. Thus, by Proposition 5.1, Assumptions A1 and A2 hold in $\mathcal{M}_m(F_0)$ if

$$
q = B + S_0 \sqrt{t} \text{ and } \delta = \delta_0(L, M)/2.
$$

We extend the definition of $c_i(x)$ to all $x \in [L, M]$ by setting $c_m = 0$ and, for $0 \leq i \leq m - 1$,

$$
c_i(x) = \sup_{Q \in \mathcal{Q}(x, F_0)} E_Q(c_{i+1} + H_{i+1}(x, \cdot)).
$$

(5.17)

By Proposition 4.3, we can calculate by backward induction $c_i(x)$ for $x \in F_0$, $0 \leq i \leq m - 1$, and probabilities $Q(x, i)$ that maximise the RHS of (5.17) in $O(n^2m)$ total time. Using the same notation for $\theta$ and $x_i$ as in Assumption A4, let $P$ be a risk-neutral probability obtained by pasting the probabilities $\mathcal{P}(\theta) = Q(x_i, i)$ in the market $\mathcal{M}_m(F_0)$. By Proposition 4.2, the super-hedging cost $c(\Psi)$ of $\Psi$ in the market $\mathcal{M}_m(F_0)$ equals $E_P(\Psi)$. Given a call option $\eta$ with maturity $k \leq m$ and payoff $\eta^*_k(S_k)$, define the function $\eta^*_k$ by backward induction on $F_0$, $0 \leq i \leq k$, by setting $\eta_k^* = \eta^*$ and, for $0 \leq i \leq k - 1$ and $x \in F_0$,

$$
\eta_k^*(x) = E_{Q(x, i)}(\eta_{k+1}^*).
$$

Using Proposition 4.2, it can be shown by backward induction that $\eta_k^*(S_0) = E_P(\eta)$. Hence, we can calculate in $O(n^2m + lmn)$ time $c(\Psi) = c_0(S_0)$ and $E_P(\phi)$. Thus A3 holds, with $T = O(n^2m + lmn)$. The first part of the theorem then follows from Theorem 3.2 and (5.3). Section H contains the remainder of the proof. \qed

In our numerical example, we set \( S_0 = $100 \), with \( L = $50 \) and \( M = $200 \). We first consider a variance swap with maturity \( T \) of one month and \( m = 20 \) daily observations. We assume the market price \( c_{m,j} \) of the call maturing at \( T \) with strike \( K_{m,j} = 65 + 5j \) is equal to the Black-and-Scholes price with the corresponding strike, maturity \( T \) and volatility \( \sigma \) for \( 1 \leq j \leq 13 \) and that no other call prices are known. Thus \( l_m = 13 \) and \( l_i = 0 \) for \( 1 \leq i < m \). We have checked numerically that \( \{L, M\} \) is acceptable. Table 5 gives the optimal super-replicating and sub-replicating prices, the computing time and the discretization error in terms of \( n \) when \( \sigma = 0.2 \).

Table 6 lists the optimal robust bounds and the computing time in terms of the volatility, and table 7 gives the amount of call positions in optimal super-replicating and sub-replicating portfolios when \( \sigma = 0.2 \). Table 8 gives the optimal super-replicating and sub-replicating prices, the computing time and the discretization error in terms of \( n \) when \( \sigma = 0.2 \), the swap and the calls mature in one year with \( m = 252 \) daily observations.

As noted before, for standard variance swaps, since \( \psi \) is not upper-bounded on \((0, M]\), it follows from (2.3) that \( \pi_{\text{sup}}((0, M]) = \infty \) for any \( M > \max(K) \). In other words, if there is no positive lower bound on stock prices, the best super-replicating price of a standard variance swap is infinite. On the other hand, Section I shows how to calculate \( \pi_{\text{inf}}((0, M]) \) using techniques similar to those of Theorem 5.3, without assuming any positive lower bound on stock prices.

5.3 Volatility swaps

As is sometimes the case in market practice, we assume for simplicity that the volatility swap payment is capped at \( \nu_{\max} \sqrt{T-1} \), where \( \nu_{\max} \) is a constant, and so the swap pays at maturity \( T \)

\[
\psi = \sqrt{T-1} \min\left(\nu_{\max}, \sqrt{\frac{1}{m} \sum_{i=1}^{m} \ln^2 \left( \frac{S_i}{S_{i-1}} \right)} \right).
\]

Table 7: Optimal super-replicating \( (b_{\sup}) \) and sub-replicating \( (b_{\inf}) \) portfolios for a variance swap when \( \sigma = 0.2 \), \( m = 20 \), and \( n = 800 \).

</table>

In order to construct the subroutine needed in Assumption A3, we will discretize both the stock price and the realized volatility. We show how to discretize the realized volatility at all time-steps. Let \( n' \) be an integer,

\[
\Lambda = \left\{ \frac{iv}{n'} ; 0 \leq i \leq n' \right\},
\]

and

\[
\rho(z) = \max\{ x \in \Lambda : x \leq z \},
\]

for \( z \geq 0 \). Define the financial derivative \( \nu_i \), \( 0 \leq i \leq m \), by induction by setting \( \nu_0 = 0 \) and

\[
\nu_{i+1} = \rho(\sqrt{\frac{\nu_i^2 + \ln^2(S_{i+1}/S_i)}{\sqrt{T}}}).
\]  

(5.18)

Consider the financial derivative \( \psi' = \nu_m \). Since the function \( \nu \mapsto \sqrt{\nu^2 + a^2} \) is 1-Lipschitz for any constant \( a \), it can be shown by induction that

\[
0 \leq \psi \sqrt{T} - \psi' \leq \frac{m\nu_{\text{max}}}{n'}.
\]  

(5.19)

Thus, \( \psi' \) is a discrete approximation of \( \psi \sqrt{T} \). Let \( \Psi' = \psi' - \beta^T \phi \). Given integer \( i \in [0, m] \), let

\[
\zeta = \psi' - \sum_{j=i+1}^{m} b_j^T f_j(S_j).
\]  

(5.20)

By (5.18), \( \psi' \) is a deterministic function of \( \nu_i \) and of \( S_j \), \( j \geq i \). Let \( \Psi'_i \) (resp. \( \zeta_i \)) denote the super-hedging cost of \( \Psi' \) (resp. \( \zeta \)) at time-step \( i \) in the market \( \mathcal{M}_m(F_0) \), where \( F_0 \) is given by (5.12). By Remark 4.2, it follows that \( \zeta_i = c_i(\nu_i, S_i) \), where \( c_i \) is a deterministic function defined on \( \Lambda \times F_0 \). By (5.20), \( c_m(\nu_m, S_m) = \nu_m \). Since \( \Psi' = \zeta - \sum_{j=1}^{i+1} b_j^T f_j(S_j) \), Remark 4.1 implies that

\[
\Psi'_i = c_i(\nu_i, S_i) - \sum_{j=1}^{i+1} b_j^T f_j(S_j).
\]

Thus, by (4.6) and (5.18),

\[
c_i(\nu_i, S_i) = \sup_{\mathcal{Q} \in \mathcal{Q}(S_i, S_0)} E_{\mathcal{Q}}(h_i(\nu_i, S_i)),
\]

(5.21)

where, for \( z > 0 \),

\[
h_i(\nu, x, z) = c_{i+1}(\rho(\sqrt{\nu^2 + \ln^2(z/x)}), z) - b_{i+1}^T f_{i+1}(S_{i+1}).
\]

We can interpret (5.21) by observing that the super-hedging cost of \( \zeta \) at time-step \( i + 1 \) is \( c_{i+1}(\nu_{i+1}, S_{i+1}) - b_{i+1}^T f_{i+1}(S_{i+1}) \), which equals \( h_i(\nu_i, S_i, S_{i+1}) \).
Denote by \( \pi_{\sup}(\{L, M\}) \) the optimal super-replicating price of \( \psi \) in the market \( \mathcal{M}_m(\{L, M\}) \) and by \( \pi_{\sup}(n, n') \) the optimal super-replicating price of \( \psi' \) in the market \( \mathcal{M}_m(F_0) \). Define similarly \( \pi_{\inf}(\{L, M\}) \) and \( \pi_{\inf}(n, n') \). Theorem 5.4 shows how to calculate \( \pi_{\sup}(n, n') \) and \( \pi_{\inf}(n, n') \) and gives an upper bound on the discretization error. The constants behind the \( \langle \rangle \) notation in (5.22), (5.23) and Section J depend on \( l, S_0 \), the calls strikes, maturities and prices, \( \nu_{\max} \), \( L \) and \( M \), but do not depend on \( n, n', m \) and \( T \).

**Theorem 5.4.** Assume that \( \{L, M\} \) is acceptable. Then \( \pi_{\sup}(n, n') \) and \( \pi_{\inf}(n, n') \) can be calculated in \( O(N(l^3 + mn'm(n+l))) \) total time with precision \( \epsilon \) via the convex program (3.3), where

\[
N = O(l \ln \left( \frac{l(1 + S_0)(1 + \nu_{\max})}{\epsilon_0(l, M)} \right)).
\]

\( V' \) has a separation oracle that runs in \( O(nn'm(n+l)) \) time. Furthermore,

\[
|\pi_{\sup}(\{L, M\}) - \pi_{\sup}(n, n')| \leq \frac{2m\nu_{\max}}{\sqrt{Tn'}} + O\left(\frac{m^2}{\sqrt{Tn'}}\right), \tag{5.22}
\]

\[
|\pi_{\inf}(\{L, M\}) - \pi_{\inf}(n, n')| \leq \frac{2m\nu_{\max}}{\sqrt{Tn'}} + O\left(\frac{m^2}{\sqrt{Tn'}}\right). \tag{5.23}
\]

**Proof.** Since \( 0 \leq \psi' \leq \nu_{\max}, \max(c(\psi'), c(-\psi')) \leq \nu_{\max} \). Thus, by Proposition 5.1, Assumptions A1 and A2 hold for \( (\psi', \phi) \) in the market \( \mathcal{M}_m(F_0) \) if

\[
q = \nu_{\max} + S_0\sqrt{I} \text{ and } \delta = \delta_0(l, M)/2. \tag{5.24}
\]

Extend the definition of \( c_i(\nu, x) = c_i(\nu, x, \beta) \) to \( i \in [0, m] \), \( \nu \in \Lambda \) and \( x \in F_0 \) by setting \( c_m(\nu, x) = \nu \) and

\[
c_i(\nu, x) = \sup_{Q \in \mathcal{Q}(x, F_0)} E_Q(h_i(\nu, x, ..)). \tag{5.25}
\]

By Proposition 4.3, we can calculate by backward induction \( c_i(\nu, x) \) for \( \nu \in \Lambda, x \in F_0 \) and \( 0 \leq i \leq m - 1 \), and probabilities \( Q(\nu, x, i) \) that maximise the RHS of (5.25) in \( O(n^2m) \) total time. Define the function with \( i \) variables \( \nu^*_i, 0 \leq i \leq m \), by induction by setting \( \nu^*_0 = 0 \) and

\[
\nu^*_i'(x_1, \ldots, x_{i+1}) = \rho\left(\sqrt{\nu^*_i(x_1, \ldots, x_i)} + \ln^2\left(\frac{x_{i+1}}{x_i}\right)\right).
\]

Note that \( \nu_i = \nu^*_i(S_1, \ldots, S_t) \). Using the same notation for \( \theta \) and \( x_1 \) as in Assumption A4, let \( P \) be a risk-neutral probability obtained by pasting the probabilities \( \mathcal{P}(\theta) = Q(\nu_i^*(\theta), x_1, i) \). By Proposition 4.2, \( E_P(\Psi') \) is equal to the super-hedging cost \( c(\Psi') \) in the market \( \mathcal{M}_m(F_0) \). Given a call option \( \eta \) with maturity \( k \leq m \) and payoff \( \eta^*(S_k) \), define the function \( \eta_i^* \) by backward induction on \( \Lambda \times F_0, 0 \leq i \leq k \), by setting \( \eta_k^*(\nu, x) = \eta^*(x) \) and, for \( 0 \leq i \leq k - 1 \), \( \nu \in \Lambda \), and \( x \in F_0 \),

\[
\eta_i^*(\nu, x) = E_Q(\nu, x, i)(\eta_k^*(\nu, x, ..)),
\]

where \( \eta_k^*(\nu, x, z) = \eta_{k+1}^*(\rho(\sqrt{\nu^2 + \ln^2(z/x)}), z) \). Using Proposition 4.2, it can be shown by backward induction that \( \eta_0^*(0, S_0) = E_P(\eta) \). Hence, we can calculate in \( O(nn'm(n+l)) \) time \( c(\Psi') = c_0(0, S_0) \) and \( E_P(\phi) \), and so A3 holds for \( (\psi', \phi) \) in the market \( \mathcal{M}_m(F_0) \), with \( T = O(nn'm(n+l)) \). The first part of the theorem then follows from Theorem 3.2 and (5.3). Section J contains the proof of (5.22) and (5.23). \( \square \)

Our numerical experiments use the same setting as in Subsection 5.2 and cap the volatility swap payoff at \( \sigma / 2.5 \). Rather than rounding with respect to \( \nu \) in the calculation of \( c_i(\nu, x) \), we have used linear interpolation, as described in Section K, which performs much better in practice. When calculating the best super-replicating price, we set \( n' = n \). When calculating the
Table 9: Optimal super-replicating and sub-replicating prices of a capped volatility swap maturing in one month. The discretization error is estimated using $n = 1600$ and $n' = 137$ for the sub-replicating price, and $n = n' = 800$ for the super-replicating price.

best sub-replicating price, we first calculate a discrete risk-neutral probability consistent with the call prices at maturity $T$ (see, e.g., (Davis and Hobson 2007)), then replace $F_0$ by another set of size $n' = n^{2/3}$ where, on each interval $I$ delimited by consecutive elements in $\{L, M\} \cup K$, the points are geometrically distributed and their number is proportional to the risk-neutral probability that $S_m$ belongs to $I$. This resulted in significantly improved performance in all our numerical experiments. Tables 9 and 12 estimate the discretization error for maturities of one month and one year, respectively. Table 10 lists the optimal super-replicating and sub-replicating prices for the swap, and Table 11 gives the amount of call positions in optimal super-replicating and sub-replicating portfolios when $\sigma = 0.2$.

5.4 Discussion of results

A discretization error of $\epsilon$ can be achieved in Theorems 5.1, 5.2, 5.3, and 5.4 by using a cutting plane algorithm with $O(\epsilon^{-1/2})$, $O(1)$, $O(\epsilon^{-1})$, and $O(\epsilon^{-3})$ running time per iteration, respectively, and so a global error of $\epsilon$ on the robust prices in the infinite space markets can be achieved with $O(\epsilon^{-1/2} \ln(\epsilon^{-1})), O(\ln(\epsilon^{-1})), O(\epsilon^{-1} \ln(\epsilon^{-1})), \text{and } O(\epsilon^{-3} \ln(\epsilon^{-1}))$ total time. Our numerical results confirm that the tradeoff between the discretization error and the running time of the robust pricing algorithms for forward start options, variance and volatility swaps is best for forward start options and worst for volatility swaps. Theorems 5.3 and 5.4 show that, for fixed $N$, $l$, and $n$ (for volatility swaps) $n'$, robust prices of variance and volatility swaps are computed in time asymptotically proportional to the number of periods $m$, as confirmed numerically in Section L. On the other hand, Tables 10 and 12 suggest that the model risk for volatility swaps is higher than that for variance swaps. This may be explained by the fact that, under a continuity assumption on the stock price, the price of a continuously-monitored variance swap can be exactly determined (Dupire 1993, Neuberger 1994) from the prices of a continuum set of co-maturing call options, which is not the case for continuously-monitored volatility swaps.

5.5 Other financial derivatives

Other financial derivatives such as lookback options, options on realized variance and realized volatility, single or double barrier options and Asian options can be handled in a similar fashion.

Consider for instance an Asian call $\psi$ that pays $\max(\frac{S_1 + \cdots + S_m}{m} - K, 0)$.

Let $F_0 = K \cup \{jM/n : 0 \leq j \leq n\}$, where $M > S_0$ and integer $n$ are fixed. Using the same techniques as before, we can show that the super-hedging cost of $\psi$ at time-step $i$ in $M_{m}(F_0)$ is

$$\Psi_i = c_i(\nu_i, S_i) - \sum_{j=1}^{i} b_{T}^{j} f_{j}(S_j),$$

where $\nu_i = \sum_{j=1}^{i-1} S_j$. The functions $c_i$ can be calculated by backward induction for $x \in F_0$ and $\nu \in [0, mM]$, by setting $c_m(\nu, x) = \max((\nu + x)/m - K, 0)$ and

$$c_i(\nu, x) = \sup_{Q \in Q(x, F_0)} E_{Q}(c_{i+1}(\nu + x, \cdot) - b_{T}^{i+1} f_{i+1}).$$

In practice, we need to discretize the values that $\nu$ can take, in the same manner as we did for volatility swaps. We can also derive optimal replicating prices and strategies for the financial derivatives considered in this section in terms of prices of moments (or of the logarithmic function) of the stock price at different maturities rather than in terms of call prices.

6 Extensions

6.1 Taking interest rates and dividends into account

Interest rates can be taken into account in the usual way by replacing each security by its discounted value. We can also incorporate deterministic dividends as well as proportional dividends in our model by replacing each security by the value of the security plus reinvested dividends, using a technique similar to the one in (Pliska 2005, SubSec 3.2.3).

6.2 Taking bid-ask spreads into account

Assume that the financial derivatives $\phi_k$, $1 \leq k \leq l$, have distinct bid and ask prices, and let $\pi^{b}$ (resp. $\pi^{a}$) be the length $l$ vector of bid (resp. ask) prices. Results in the preceding sections can be easily extended to this case. We have for instance the following.
Theorem 6.1. If assumptions A1 and A3 hold and there is a risk-neutral probability $P$ such that

$$E_P(\phi) \in [\pi^b + \delta 1_1, \pi^a - \delta 1_1]$$

and $-q \leq E_P(\psi)$, then $\pi_{\text{sup}}$ can be calculated via the convex program with $2l + 1$ variables

$$\pi_{\text{sup}} = \inf_{(\beta^a, \beta^b, \gamma) \in V''} a_0^T(\beta^a, \beta^b, \gamma),$$

where $a_0 = (\pi^a, -\pi^b, 1)$, and

$$V'' = \{(\beta^a, \beta^b, \gamma) \in \mathbb{R}^{+l} \times \mathbb{R}^{+l} \times \mathbb{R} : a_0^T(\beta^a, \beta^b, \gamma) \leq q + 1, (\beta^a - \beta^b, \gamma) \in V\}.$$

Furthermore, for $(\beta^a, \beta^b, \gamma) \in V''$,

$$||((\beta^a, \beta^b, \gamma)|| \leq \frac{4(1 + q)\sqrt{2}(1 + ||(\pi^a, \pi^b)||)}{\delta},$$

$V''$ contains a ball of radius $r = \delta||a_0||^{-1}l^{-1/2}/3$ centered at $(r 1_{2l}, q + \delta)$, and admits a separation oracle that runs in $T + O(1)$ time, where $T$ is the running time of the subroutine in Assumption A3.

The vector $\beta^a$ (resp. $\beta^b$) represents the amount of assets bought (resp. sold) in order to super-replicate $\psi$.

### 6.3 Limiting the jump sizes or the realized volatility

We can tighten the bounds on the price of $\psi$ by limiting the underlying dynamics. Limitations to the up and/or down jumps can be achieved by limiting the set $D(\theta)$ in (4.5) to the securities values that respect these limitations. For instance, if the log-returns are constrained to be at most $3\sigma \sqrt{T/m}$ in absolute value at any time-step, $Q$ must be supported on the set

$$\{z \in F_0 : |\ln(z)| \leq 3\sigma \sqrt{T/m}\}$$

in (5.25), and the best sub-replicating price for volatility swaps becomes 10.70% when $\sigma = 0.2$. We can upper-limit the realized volatility to $\sigma \sqrt{2.5}$ by setting the payoff at maturity to $-\infty$ if the realized volatility exceeds $\sigma \sqrt{2.5}$ and keeping the remaining calculations unchanged, which yields a best sub-replicating price of 13.09%. If both the log-returns and the realized volatility are required to satisfy the previous constrains, the best sub-replicating price becomes 13.95%, while the best super-replicating price remains essentially the same as in the un-constrained case. These prices have been calculated using the same setting as in Table 10. The running times for the three experiments were respectively 432, 614, and 463 seconds.

### 6.4 Portfolios of financial derivatives

Consider a portfolio of financial derivatives. Using (2.3), it can be shown that the optimal super-replicating (resp. sub-replicating) portfolio price given other derivatives prices is at most (resp. at least) the sum of the optimal super-replicating (resp. sub-replicating) prices of the portfolio components. Using the same setting as in Table 8 with $n = 800$, Table 13 lists the optimal super-replicating and sub-replicating prices for a standard variance swap, a variance swap where $H(x, y) = T^{-1}(y/x - 1)^2$, and the average of the two swaps. The gap between $\pi_{\text{inf}}$ and $\pi_{\text{sup}}$ for the average variance swap turned out to be less than that for each component. In general, our method allows the efficient calculation of optimal robust bounds on a portfolio of derivatives of the type considered in Section 5, such as barrier options with different barrier levels and strikes.
Table 13: Optimal super-replicating and sub-replicating prices for variance swaps based on Log-returns, returns, and their average, with $n = 800$. The running times ranged from 327 to 369 seconds.

7 Conclusion

We have shown that optimal super-replicating and sub-replicating prices and corresponding hedging portfolios can be calculated efficiently for a wide variety of exotic financial derivatives in terms of liquid financial derivatives in a discrete-time setting. The main novelty behind our approach is the use of convex programs, which are solved via cutting planes generated by risk-neutral probabilities. Super-hedging costs are calculated via recursive evaluations of concave envelopes. We have implemented our method using an analytic center cutting plane algorithm and an optimized convex hull algorithm. Numerical calculations of optimal super-replicating and sub-replicating prices in terms of call options were given for forward start options, variance and volatility swaps. In our examples, we have discretized the state-space and gave theoretical and empirical bounds on the discretization errors. These prices are close to those obtained by a standard model in some cases and differ considerably from them in other cases. Our method is much more flexible than known explicit methods: it can incorporate interest rates and dividends, bid-ask spreads, limitations to the jumps or to the realized volatility of the underlying assets, and can be used to calculate efficiently optimal prices on portfolio of options of certain type. It can be applied to multi-period financial derivatives on multiple assets but, in general, the corresponding running time is exponential in the number of assets. This is because, in general, the number of points needed to discretize the possible values of the assets vector is exponential in the number of assets.

8 Acknowledgments

This paper has been presented at the 30th French Finance Association Conference, the European Financial Management Association 2013 Annual Meetings, and the Advances in Financial Mathematics 2014 conference in Paris. The author thanks seminar participants, two anonymous referees, an anonymous associate editor, and Gustavo Manso (department editor), for helpful comments and suggestions. This work was achieved through the Laboratory of Excellence on Financial Regulation (Labex ReFi) under the reference ANR-10-LABX-0095. It benefitted from a French government support managed by the National Research Agency (ANR).

References

A Proof of Lemma 3.1

By Assumption A2 and (3.2), $V \subseteq \mathcal{E}$, and so $V' \subseteq \mathcal{E}'$. For $(\beta, \gamma) \in \mathcal{E}'$ and $1 \leq i \leq l$, it follows from (3.4) that $-q \leq \beta^T \pi + \gamma + \delta \beta_i$. Thus, by (3.5), $-q \leq q + 1 + \delta \beta_i$, and so $|\beta_i| \leq R_0$. Hence $||\beta|| \leq R_0 \sqrt{l}$. On the other hand, (3.4) implies that $-q \leq \beta^T \pi + \gamma$ which, together with (3.5), shows that $|\gamma| \leq q + 1 + |\beta^T \pi|$. By the Cauchy-Schwartz inequality, it follows that $|\gamma| \leq q + 1 + ||\pi|| \sqrt{l}$.

Since $||(\beta, \gamma)|| \leq ||\beta|| + |\gamma|$ and $q + 1 \leq R_0$, we conclude that $||(\beta, \gamma)|| \leq R_1$.

Consider now a vector $(\beta, \gamma) \in \mathbb{R}^l \times \mathbb{R}$ that belongs to the ball of radius $r = \delta(1 + ||\pi||)^{-1}$ centered at $(0_1, q + \delta)$. Since $||(\beta, q + \delta - \gamma)|| \leq r \leq \delta$, $||\beta|| \leq \delta$ and $q \leq \gamma$. Thus, by Assumption A1 and (2.4), $(\beta, \gamma) \in V$. On the other hand, since

$$a_0^T (\beta, \gamma) = a_0^T (\beta, \gamma - q - \delta) + q + \delta,$$

where $a_0 = (\pi, 1)$, it follows from the Cauchy-Schwartz inequality that $a_0^T (\beta, \gamma) \leq r ||a_0|| + q + \delta$. Since $||a_0|| \leq 1 + ||\pi||$, we conclude that $a_0^T (\beta, \gamma) \leq q + 1$. Hence $(\beta, \gamma) \in V'$. \hfill \Box

B Proof of Lemma 3.2

For shorthand, denote a vector $(\beta, \gamma) \in \mathbb{R}^l \times \mathbb{R}$ by $x$. Let

$$K = \{x \in \mathbb{R}^{l+1} : a_i^T x \leq a_i^T x \text{ for } i \in I'\},$$

$$K' = \{x \in K : a_0^T x \leq q + 1\},$$

By (3.9) and (3.10) and linear program duality, $b_0 = \inf_{x \in K} a_0^T x$.
Note that the last 2l constraints in the RHS of (B.1) are the same as those in (3.4). Thus,

\[ K = \{ x \in E : a_i' \leq a_i^T x \text{ for } i \in I \}, \]

\[ K' = \{ x \in E' : a_i' \leq a_i^T x \text{ for } i \in I \}. \]

But \( E' \subseteq R_0 \) since \( B(0, R_1) \subseteq R_0 \) and, by Lemma 3.1, \( E' \subseteq B(0, R_1) \). As

\[ \tilde{C} = \{ x \in R_0 : a_i' \leq a_i^T x \text{ for } i \in I \}, \]

we conclude that \( K' = E' \cap \tilde{C} \). Since \( V' \subseteq E' \) by Lemma 3.1 and \( V' \subseteq \tilde{C} \), it follows that \( V' \subseteq K' \) and so \( K' \) is non-empty. Thus, by (B.2) and (B.3), \( b_0 = \inf_{x \in K'} a_i^T x \). Since \( K' \subseteq \tilde{C} \), this concludes the proof. \( \square \)

C Proof of Proposition 4.1

By Assumption A4, \( x_i \) is a convex combination of elements of \( D(\theta) \), and so \( Q(x_i, D(\theta)) \) is non-empty. (4.6) follows immediately from (4.1). By (2.1), for any \( \epsilon > 0 \), there is a gains function \( g = \sum_{j=1}^{m} \xi_j^T (X_j - X_{j-1}) \) such that \( \Psi \) is upper-bounded by \( c(\Psi) + \epsilon + g \). Note that, for \( j \in [1, m] \), there is a deterministic function \( \xi_j^* \) on \( D_{j-1} \) such that \( \xi_j = \xi_j^*(X_1, \ldots, X_{j-1}) \). We show by backward induction that

\[ \Psi_i \leq c(\Psi) + \epsilon + \sum_{j=1}^{i} \xi_j^T (X_j - X_{j-1}). \quad (C.1) \]

(C.1) clearly holds when \( i = m \). If it holds for \( i + 1 \) then, for \( \theta = (x_1, \ldots, x_i) \in D_i \) and \( x \in D(\theta) \),

\[ \Psi_{i+1}^*(\theta, x) \leq c(\Psi) + \epsilon + \xi_{i+1}^* T (x - x_i) + \sum_{j=1}^{i} \xi_j^* T (x_j - x_{j-1}), \quad (C.2) \]

where we denote \( \xi_j^*(x_1, \ldots, x_{j-1}) \) by \( \xi_j^* \) for shorthand. Since the RHS of (C.2) is a linear function of \( x \), it upper bounds \( \Psi_{i+1}(\theta, \cdot)(x) \) for \( x \in D(\theta) \). Hence \( \Psi_i^*(\theta) \) is well defined,

\[ \Psi_i^*(\theta) \leq c(\Psi) + \epsilon + \sum_{j=1}^{i} \xi_j^* T (x_j - x_{j-1}), \]

and (C.1) holds for \( i \). Thus \( \Psi_0 \leq c(\Psi) \).

Conversely, for \( 0 \leq i \leq m - 1 \), by the definition of \( \Psi_i^* \) and (4.4), there is a financial derivative \( \xi_{i+1} \) which is a function of \( X_0, \ldots, X_i \) such that

\[ \Psi_{i+1} \leq \xi_{i+1}^T (X_{i+1} - X_i) + \Psi_i. \]

Hence there is a gains function \( g \) such that \( \Psi \leq g + \Psi_0 \). Thus \( c(\Psi) \leq \Psi_0 \), and so \( \Psi_0 = c(\Psi) \). \( \square \)

D Proof of Proposition 4.2

For \( (x_1, \ldots, x_m) \in D_m \), choose a state \( \omega \in \Omega \) such that \( X_j(\omega) = x_j \) for \( 1 \leq j \leq m \), and set

\[ P(\{\omega\}) = \Pi_{i=1}^{m} P_{(x_1, \ldots, x_{i-1})}(\{x_i\}). \]
The reader can verify that $P$ is a probability, and that $E_P(\eta) = \eta^*_g(\theta)$ if $\eta^*$ is the indicator function of a path $\theta \in D_m$. By linearity of expectations, if follows that $E_P(\eta) = \eta^*_0(\theta)$ for any function $\eta^*$. Let $\eta = \sum_{j=1}^m \xi_j^2 (X_j - X_{j-1})$ be a gains function. Using backward induction and (4.7), it can be shown that, for $0 \leq i \leq m$,

$$\eta^*_i(X_1, \ldots, X_i) = \sum_{j=1}^i \xi_j^2 (X_j - X_{j-1}).$$

Thus $E_P(\eta) = 0$ and $P$ is risk-neutral.

Assume now that $P(\eta)$ attains the RHS of (4.6). It can be shown by backward induction that $\Psi_1^*$ is defined as in Proposition 4.1 and $\Psi_i$ is the sequence obtained by replacing $\eta^*$ with $\Psi^*$ in (4.7), and so $\Psi_0 = E_P(\psi)$. □

E Proof of Proposition 5.1

Assume that $\delta$ and $q$ satisfy the conditions in Proposition 5.1. For any given integers $i_0 \in [1, m]$ and $j_0 \in [1, l_i]$, if $c_{i_0,j_0}$ is replaced with $c_{i_0,j_0} \pm \delta$ and the other call prices remain unchanged, then (5.2) still holds. On the other hand, it follows from the proof of (Davis and Hobson 2007, Theorem 4.2) that, if (5.2) holds, there is a risk-neutral probability $P$ supported on $\mathcal{K} \cup \{k_\ast, k^\ast\}$ such that $E_P(\max(0, S_i - K_{i,j})) = c_{i,j}$ for $1 \leq i \leq m$ and $1 \leq j \leq l_i$. Using Remark 3.1, we conclude that $A2$ holds. Furthermore, $c(\Psi) \leq c(\psi) + ||\beta||_1 S_0$, since $c$ is sub-additive and since the super-hedging cost of a call is at most $S_0$. Since, by the Cauchy-Schwartz inequality, $||\beta||_1 \leq \sqrt{i} ||\beta||$,

$$c(\Psi) \leq c(\psi) + \sqrt{i} ||\beta|| S_0,$$

and so Assumption $A1$ holds as well. On the other hand, it follows from (5.2) that, since $c_{i,0}$ and $c_{i,l_i+1}$ are upper-bounded by $S_0$, so is $c_{i,j}$. Hence (5.3). □

F Remainder of the proof of Theorem 5.1

Let $\mathcal{M}'$ be a market with sample space $\Omega'$. We say that a market $\mathcal{M}$ is a sub-market of $\mathcal{M}'$ if it is obtained by restricting the basic securities of $\mathcal{M}'$ to a non-empty subset $\Omega$ of $\Omega'$. To simplify the notation, if $\eta$ is a derivative in $\mathcal{M}'$, the restriction of $\eta$ to $\Omega$ is also denoted by $\eta$. To upper-bound the discretization errors in Theorems 5.1, 5.2, 5.3, and 5.4, we will use the following result, where $\mathcal{M}$ (resp. $\mathcal{M}'$) is a market with finite (resp. infinite) state-space, and prove (F.1) by extending a hedging scheme from $\mathcal{M}$ to $\mathcal{M}'$. The proofs of Theorems 5.1, 5.2, 5.3, and 5.4 thus allow us to construct hedging strategies in $\mathcal{M}'$ which are optimal, up to $\epsilon$ and the discretization error.

**Proposition F.1.** Let $\psi$ be a derivative in $\mathcal{M}'$, $\phi$ a vector of derivatives in $\mathcal{M}'$, and $\mathcal{M}$ a sub-market of $\mathcal{M}'$. Assume that Assumptions $A1$, $A2$ and $A3$ hold for $(\psi, \phi)$ in the market $\mathcal{M}$, and

$$c(\psi - \beta^T \phi; \mathcal{M}') \leq c(\psi - \beta^T \phi; \mathcal{M}) + \alpha,$$

for $||\beta||_\infty \leq R_0$ and some constant $\alpha$. Then

$$\pi_{\sup}(\psi, \phi; \mathcal{M}') \leq \pi_{\sup}(\psi, \phi; \mathcal{M}) \leq \pi_{\sup}(\psi, \phi; \mathcal{M}') + \alpha.$$  

**Proof.** For a derivative $\eta$ in $\mathcal{M}'$ and a constant $\gamma$, if $\eta \leq \gamma$ in $\mathcal{M}'$, then $\eta \leq \gamma$ in $\mathcal{M}$. Hence, $V_0(\psi, \phi; \mathcal{M}') \leq V_0(\psi, \phi; \mathcal{M})$. By (2.3), the first inequality in (F.2) follows. We now show the
second one. By Theorem 3.2, for \( \epsilon > 0 \), there is \((\beta^*, \gamma^*) \in V(\psi, \phi; \mathcal{M})\) with \( \|\beta^*\|_\infty \leq R_0 \) such that
\[
\beta^* T \pi + \gamma^* \leq \pi_{\text{sup}}(\psi, \phi; \mathcal{M}) + \epsilon.
\]
By (2.4), \( c(\psi - \beta^* T \phi; \mathcal{M}) \leq \gamma^* \), and so \( c(\psi - \beta^* T \phi; \mathcal{M}) \leq \gamma^* + \alpha \). Thus, \((\beta^*, \gamma^* + \alpha) \in V(\psi, \phi; \mathcal{M}')\). Since
\[
\beta^* T \pi + \gamma^* + \alpha \leq \pi_{\text{sup}}(\psi, \phi; \mathcal{M}) + \alpha + \epsilon,
\]
we infer, by applying (2.5) in the market \( \mathcal{M}' \), that \( \pi_{\text{sup}}(\psi, \phi; \mathcal{M}') \leq \pi_{\text{sup}}(\psi, \phi; \mathcal{M}) + \alpha + \epsilon \). Letting \( \epsilon \) go to 0 concludes the proof. \( \square \)

For any finite subset \( F \) of \( \mathbb{R} \), let \( F^* = F \cup \{\max(F), \infty\} \). Denote by \( g_{|F^*} \) the restriction of \( g \) to a subset \( F' \) of \( \mathbb{R} \). By convention, \( \max(\emptyset) = -\infty \).

**Proposition F.2.** Let \( F \) be a finite subset of \( \mathbb{R}^+ \) containing \( \{0\} \), and \( g \) a function on \( \mathbb{R}^+ \) which is convex on any closed interval delimited by consecutive points in \( F \). Then \( \overline{g}(x) = \overline{g}_{|F^*}(x) \), for \( x \geq 0 \).

**Proof.** The proposition follows by observing that a concave function upper-bounds \( g \) on \( \mathbb{R}^+ \) if and only if it upper-bounds \( g \) on \( F^* \). \( \square \)

**Proposition F.3.** Let \( w \geq 0 \) and \((g_j), j \in J \), a finite family of continuous functions on an interval \([y, z]\) such that, for \( j \in J \), \( g_j^* \) exists on \((y, z)\) and is lower-bounded by \(-w\). Let \( f = \max_{j \in J}(g_j) \). If \( f(x) \leq g(x) \) for \( x \in \{y, z\} \), where \( g \) is a linear function, then \( f(x) \leq g(x) + w(z - y)^2/8 \) for \( x \in [y, z] \).

**Proof.** The proposition follows by observing that the function \( x \mapsto g_j(x) + w(x - y)(x - z)/2 \) is convex and is upper-bounded by \( g \) on \( \{y, z\} \). Thus it is thus upper-bounded by \( g \) on \([y, z]\), and so \( g_j \) is upper-bounded by \( g + w(z - y)^2/8 \) on \([y, z]\). \( \square \)

**Lemma F.1.** Let \( F \) be a finite subset of \( \mathbb{R}^+ \) with \( |F| > 1 \), and \( g \) a function on \([\min(F), \infty)\) which is convex on \([\max(F), \infty)\) and such that \( g(u) = \lambda u + \lambda' \) for \( u \geq x' \), for some constants \( x' \geq \max(F) \), \( \lambda \) and \( \lambda' \). Then, for \( x \geq \min(F) \),
\[
\overline{g}_{|F}(x) = \max_{u, u' \in F, u \leq u', u \neq u'} \frac{(u' - x)g(u) + (x - u)g(u')}{u' - u}, \tag{F.3}
\]
with the convention that \( \overline{g}_{|F}(x) = -\infty \) if \( x > \max(F) \). Furthermore,
\[
\overline{g}_{|F^*}(x) = \max(\overline{g}_{|F}(x), \max_{u \in F, u \leq x} g(u) + \lambda(x - u)), \tag{F.4}
\]
and there is a real number \( \xi^* \) such that, for \( y \in F^* \),
\[
g(y) \leq \overline{g}_{|F^*}(x) + \xi^*(y - x). \tag{F.5}
\]
If \( \min(F) \leq x \leq x' \) and \( x' = \max(F) \), then
\[
0 \leq \overline{g}_{|F^*}(x) - \overline{g}_{|F}(x) \leq \frac{x}{x'} \max_{u \in F, u < x} (|\lambda u + \lambda' - g(u)|). \tag{F.6}
\]

**Proof.** By Proposition 4.3, we can assume the probabilities \( Q \) in (4.1) to be supported on two distinct points \( u \) and \( u' \) when \( d = 1 \), with \( u \leq x \leq u' \), which gives (F.3). On the other hand, since \( g \) is convex on \([\max(F), \infty)\), for \( \max(F) < y < u' \),
\[
\frac{g(y) - g(\max(F))}{y - \max(F)} \leq \frac{g(y) - g(u')}{y - u'}.
\]
Similarly, for $u, u' \in F^*$, $u \leq x \leq u', u \neq u'$,
\[ \frac{g_y(x')}{x'} \geq \frac{(u' - x)g(u) + (x - u)g(u')}{u' - u}. \]

Letting $u'$ go to infinity implies that $g_y(x') \geq g(u) + \lambda(x - u)$. Hence $A(x) \leq g_y(x')$, where $A(x)$ is the RHS of (F.4).

Assume now $x \in [\min(F), \max(F)]$. By Proposition 4.3, there is a real number $\zeta$ such that, for $y \in F$,
\[ g(y) \leq g(x) + \zeta(y - x). \]

Let $\xi^* = \max(\lambda, \zeta)$ and $y \in F$. Since $g_y(x) \leq A(x)$, if $y \geq x$ or if $\xi^* = \zeta$,
\[ g(y) \leq A(x) + \xi^*(y - x). \]

Also, it follows from the definition of $A(x)$ that (F.8) holds if $y < x$ and $\xi^* = \lambda$. Thus, (F.8) holds for any $y \in F$.

Similarly, if $x \geq \max(F)$, let $\xi^* = \lambda$. It follows from the definition of $A(x)$ that (F.8) holds for $y \in F$. We conclude that, for $x \geq \min(F)$, there is $\xi^* \geq \lambda$ such that (F.8) holds for $y \in F$. In particular,
\[ g(\max(F)) \leq A(x) + \xi^*(\max(F) - x), \]

which, by (F.7), implies that (F.8) holds for $y \in F^*$. Hence $g_y(x') \leq A(x)$. This implies that (F.4) and (F.5) hold.

We now prove (F.6). By (F.3) and (F.4),
\[ g_y(x') = \max(g_y(x), \max_{u \in F, u < x} g(u) + \lambda(x - u)). \]

On the other hand, for $u \in F$ with $u < x \leq x'$,
\[
\begin{align*}
g_y(x) + \lambda(x - u) & = \frac{(x' - x)g(u) + (x - u)g(x')}{x' - u} + \frac{x - u}{x' - u}(g(u) - \lambda u - \lambda') \\
& \leq \frac{x}{x'} \left( g_y(x) \right) + \max_{u' \in F, u' < x} (\lambda u + \lambda' - g(u')).
\end{align*}
\]

This concludes the proof.

We now prove the remainder of the theorem. Set $K_{2,0} = 0$, $M_0 = \max(K)$, and $M_i = \max(F_i)$ for $1 \leq i \leq 2$. Assume that $\beta = (b_1, b_2)$ is such that $|\beta|_\infty \leq R_0$. By (5.9), $R_0 = O(1)$.

Since $|x - K_{i,j}, 0| - x| \leq M_0$ for $x \geq 0, 1 \leq i \leq 2$ and $1 \leq j \leq l_i$,
\[ |b_i^T f_i(x) - (b_i^T 1_{l_i}) x| \leq R_0 M_0 l_i, \]

and so, for $x_1 \geq 0$, $x_2 \geq 0$,
\[ \Psi^*(x_1, x_2) = \max(0, x_2 - x_1) - b_2^T 1_{l_2} x_2 - b_1^T 1_{l_1} x_1 + O(1). \]

It follows from (5.4) that, for $x_1 \in F_1$,
\[ \Psi^*(x_1; F_2) = \Psi^*(x_1, .)|_{F_2}(x_1). \]

Similarly, for $x_1 \geq 0, \Psi^*_1(x_1) = \Psi^*(x_1, .)(x_1)$. Since $g = \Psi^*(x_1, .)$ is convex on each interval $[K_{2,j}, K_{2,j+1}], 0 \leq j \leq l_2 - 1$, it follows by applying Proposition F.2 with $F = F_2$ that
\[ \Psi^*_1(x_1) = \Psi^*(x_1, .)|_{F_2}(x_1). \]
Since $g$ is convex on $[M_2, \infty)$, it satisfies the conditions of Lemma F.1 with $F = F_2$, $x' = \max(M_2, x_1)$. Furthermore, by (F.9), $\lambda = O(1)$, $\lambda' = O(1 + x_1)$ and $\Psi^*(x, u) = O(1 + x_1)$ for $u \leq M_0$. Hence, by (F.6), (F.10) and (F.11), for $x_1 \in F_1$ and some constant $\kappa = O(1)$,

$$0 \leq \Psi_1^*(x_1) - \Psi_1^*(x_1; F_2) \leq \kappa x_1 e'. \tag{F.12}$$

Also, by (F.5) and (F.11), for $x_1 \geq 0$, there is a real number $\xi_{x_1}^*$ such that, for $x_2 \in F_2^*$,

$$\Psi^*(x_1, x_2) \leq \Psi_1^*(x_1) + \xi_{x_1}^* (x_2 - x_1). \tag{F.13}$$

Since $g$ is convex on any interval delimited by consecutive points of $F_2$, (F.13) holds for $x_2 \geq 0$. On the other hand, the function $g$ satisfies the conditions of Lemma F.1 with $F = \{0\} \cup \mathcal{K}$, $x' = \max(M_0, x_1)$, and $\lambda = 1 - b_2^2 u_{1_2}$. Let $K_{j'}', 0 \leq j' \leq l'$, denote the elements of $F$ in increasing order, with $K_{l'+1} = \infty$. (F.3), (F.4) and (F.11) imply that, for $x_1 \in [K_{j'}, K_{j'+1}^*), 0 \leq j \leq l'$,

$$\Psi_1^*(x_1) = \max(\max_{0 \leq j' \leq j} f_{j', j''}(x_1), \max_{0 \leq j' \leq j} \Psi^*(x_1, K_{j'}')) + (1 - b_2^2 u_{1_2}) (x_1 - K_{j'}'), \tag{F.14}$$

where

$$f_{j', j''}(x_1) = \frac{(K_{j'}' - x_1) \Psi^*(x_1, K_{j'}') + (x_1 - K_{j'}') \Psi^*(x_1, K_{j''}')} {K_{j''} - K_{j'}'}. \tag{F.15}$$

It follows that $\Psi_1^*(x_1) = O(1)$ for $x_1 \in [0, M_0)$, since, by (F.9), $\Psi^*(x_1, K_{j''}) = O(1)$ for $0 \leq j' \leq l'$. Furthermore, since $\Psi^*(x_1, K_{j''})$ and $\Psi^*(x_1, K'_{j'})$ are linear functions of $x_1$ with $O(1)$ slope on $(K_{j'}, K_{j'+1}^*)$,

$$f_{j', j''}(x_1) = O(1), \tag{F.16}$$

for $x_1 \in (K_{j'}, K_{j'+1}^*)$. Moreover, by (F.9), $\Psi^*(, K_{j''})$ is linear with slope $-b_2^2 u_{1_2}$ on $[M_0, \infty)$ and so, by (F.14), the function $\Psi_1^*$ is also linear on $[M_0, \infty)$ and satisfies the conditions of Lemma F.1 with $F = F_1$, $x' = M_1$, $\lambda = 1 - b_2^2 u_{1_2} - b_2^2 u_{1_2}$. Note that $\lambda$ and $\lambda' = \Psi_1^*(M_0) - \lambda M_0$ are $O(1)$. Hence, by (F.6),

$$\Psi_{1|F_1}(S_0) = \frac{\Psi_{1|F_1}(S_0)} {\Psi_{1|F_1}(S_0)} + O(\epsilon'), \tag{F.17}$$

and there is a real number $\xi_0^*$ such that, for $x_1 \in F_1^*$,

$$\Psi_1^*(x_1) \leq \Psi_{1|F_1}(S_0) + \xi_0^* (x_1 - S_0). \tag{F.18}$$

Consider now a probability $Q \in \mathcal{Q}(S_0, F_1)$. By (F.12),

$$E_Q(\Psi_1^*) = E_Q(\Psi_1^*(, F_2)) + O(\epsilon').$$

Hence, by (4.1) and (5.5) and taking the supremum over $Q \in \mathcal{Q}(S_0, F_1)$, it follows that

$$\Psi_{1|F_1}(S_0) = c(\Psi; M(F_1, F_2)) + O(\epsilon'),$$

and so, by (F.17),

$$\Psi_{1|F_1}(S_0) = c(\Psi; M(F_1, F_2)) + O(\epsilon'). \tag{F.19}$$

Since (F.18) holds for $x_1 \in \{M_0, M_1\}$ and $\Psi_1^*$ is linear on $[M_0, M_1]$, (F.18) holds for $x_1 \in [M_0, M_1]$; and so it holds for $x_1 \in F_1 \cup [M_0, \infty)$. Using (F.14), (F.16) and Proposition (F.3), we conclude that, for $x_1 \geq 0$,

$$\Psi_1^*(x_1) \leq \Psi_{1|F_1}(S_0) + \xi_0^* (x_1 - S_0) + O(n^{-2}). \tag{F.17}$$

Using (F.13) and (F.19), we infer that, for $x_1 \geq 0$ and $x_2 \geq 0$,

$$\Psi^*(x_1, x_2) \leq c(\Psi; M(F_1, F_2)) + \xi_0^*(x_1 - S_0) + \xi_{x_1}^* (x_2 - x_1) + O(n^{-2} + \epsilon').$$

Thus, $c(\Psi; M_2(R^+)) \leq c(\Psi; M(F_1, F_2)) + O(n^{-2} + \epsilon')$, which, by Proposition F.1, implies (5.8).
G Remainder of the proof of Theorem 5.2

Since $\Psi^*(x_1, x_2)$ is a convex function of $x_2$ on any interval of positive real numbers disjoint with $\mathcal{K}$ and not containing $x_1$, it can be shown using arguments similar to those in the proof of Theorem 5.1 that, for $x_1 \in [K'_j, K'_{j+1})$, $0 \leq j \leq l'$,

$$
\Psi_1^1(x_1) = \max(\Psi^*(x_1, x_1), \max_{0 \leq j' < j'' \leq t_2} f_{j', j''}(x_1), \max_{0 \leq j' < j} \Psi^*(x_1, K'_j) - (1 + b_{j}^T \mathbf{1}_{l_2})(x_1 - K'_j)),
$$

where $f_{j', j''}$ is given by (F.15). Hence, on each interval $I$ delimited by two consecutive points in $\{0\} \cup \mathcal{K}$, the function $\Psi_1^1$ is convex, since $f_{j', j''}$ is convex on $I$, and $\Psi_1^1$ is linear on $[\max(\mathcal{K}), \infty)$. Thus, by Proposition F.2 and Lemma F.1, we can calculate $c(\Psi; \mathcal{M}_2(\mathbb{R}^+))$ in terms of the slope of $\Psi_1^1$ on $[\max(\mathcal{K}), \infty)$ and the values of $\Psi_1^1$ on $\{0\} \cup \mathcal{K}$. We can then show (5.10) by arguments similar to those in the proof of Theorem 5.1. \qed

H Remainder of the proof of Theorem 5.3

The following lemma shows that, under smoothness conditions on $H$, $\pi_{\text{sup}}([L, M])$ is well approximated by $\pi_{\text{sup}}(F_0)$.

**Lemma H.1.** Assume that $H$ is continuous on $[L, M]^2$ and there are functions $a$ and $b$ on $(L, M)$, and $w \geq 0$, such that the following conditions hold. The function $a$ is non-positive. For $x \in [L, M]$, the function $y \mapsto H(x, y)$ has a second derivative lower-bounded by $b(y)$ for $y \in (L, M)$. If $y$ and $z$ are two elements of $F_0$ and $y < x < z$, the second derivative of $(z - x)H(x, y) + (x - y)H(x, z)$ with respect to $x$ is lower bounded by $(z - y)a(x)$. Furthermore, $(a(x) + b(x))(z - y)^2 \geq -w$, if $y$ and $z$ are consecutive elements of $F_0$. Then

$$
\pi_{\text{sup}}(F_0) \leq \pi_{\text{sup}}([L, M]) \leq \pi_{\text{sup}}(F_0) + \frac{w}{8}.
$$

**Proof.** Let $i \in [1, m - 1]$ and $x \in [y, z]$, where $y$ and $z$ are consecutive elements of $F_0$. By Proposition 4.3, we can assume the probability $Q$ in (5.17) to be supported by two points $y'$ and $z'$, and so

$$
c_i(x) = \max_{y', z' \in F_0, y' < y < z' \leq z'} g_{i, y', z'}(x), \quad (H.1)
$$

where

$$
g_{i, y', z'}(x) = \frac{z' - x}{z' - y'} (c_{i+1}(y') + H_{i+1}(x, y')) + \frac{x - y'}{z' - y'} (c_{i+1}(z') + H_{i+1}(x, z')). \quad (H.2)
$$

Note that (H.1) also holds if $i = m$ and $g_{m, y', z'}$ is the null function. Thus, for $1 \leq i \leq m$ and $x_0 \in [L, M]$,

$$
c_i(x) + H_i(x_0, x) = \max_{y', z' \in F_0, y' < y < z' \leq z'} f_{i, x_0, y', z'}(x),
$$

where

$$
f_{i, x_0, y', z'}(x) = g_{i, y', z'}(x) + H_i(x, x_0).
$$

On the other hand, by (4.8) and (5.17), there is a real number $\xi_{i, x_0}$ be such that, for $x \in F_0$,

$$
c_i(x) + H_i(x_0, x) \leq c_{i-1}(x_0) + \xi_{i, x_0}(x - x_0).
$$

Furthermore, by (H.2), $g_{i, y', z'}$ is continuous on $[y, z]$ and $g_{i, y', z'}''(x) \geq a(x)$ for $x \in (y, z)$. Hence $f_{i, x_0, y', z'}$ is continuous on $[y, z]$ and $f_{i, x_0, y', z'}''(x) \geq a(x) + b(x)$ for $x \in (y, z)$. Since $f_{i, x_0, y', z'}'' \geq -w/(z - y)^2$ on $(y, z)$, by Proposition F.3, we conclude that, for $x \in [y, z]$,

$$
c_i(x) + H_i(x_0, x) \leq c_{i-1}(x_0) + \xi_{i, x_0}(x - x_0) + \frac{w}{8}, \quad (H.3)
$$

33
Thus, in the market \(\mathcal{M}_{[L,M]}\),

\[
c_i(S_i) + H_i(S_{i-1}, S_i) \leq c_{i-1}(S_{i-1}) + \xi_i(S_i - S_{i-1}) + \frac{w}{8},
\]  

(H.4)

where \(\xi_i\) is the financial derivative \(\xi_i = \xi^*_{i,S_{i-1}}\). By (5.11) and summing (H.4) for \(i \in [1, m]\), we infer that

\[
\Psi \leq c_0(S_0) + \sum_{i=1}^{m} \xi_i(S_i - S_{i-1}) + m \frac{w}{8}.
\]

On the other hand, by applying (5.13) with \(i = 0\), it follows that

\[
c_0(S_0) = c(\Psi; \mathcal{M}_m(F_0)).
\]

(H.5)

Thus,

\[
c(\Psi; \mathcal{M}_m([L, M])) \leq c(\Psi; \mathcal{M}_m(F_0)) + m \frac{w}{8}.
\]

We conclude the proof using Proposition F.1.

We now prove (5.15) and (5.16). Let \(H(x, y) = T^{-1} \ln^2(y/x)\). Then

\[
\frac{\partial^2 H}{\partial y^2}(x, y) = 2T^{-1} \frac{1 + \ln(x/y)}{y^2},
\]

(H.6)

and the second derivative of \((z - x)H(x, y) + (x - y)H(x, z))/(z - y)\) with respect to \(x\) is

\[
2 \left( T^{-1} - \frac{(z + x) \ln(x/y) + (x + y) \ln(z/x)}{(z - y)} \right).
\]

By noting that \(x + y \leq x + z \leq 2z\) if \(y < x < z\), and that the function \(z \ln(z/y)/(z - y)\) is increasing with respect to \(z\) and decreasing with respect to \(y\) for \(0 < y < z\), a standard calculation shows that the conditions of Lemma H.1 hold with

\[
\begin{align*}
  a(x) &= -\frac{4}{x^2} T^{-1} \frac{M \ln(M/L)}{M - L}, \\
  b(y) &= -\frac{2}{y^2} T^{-1} \ln(M/L), \text{ and} \\
  w &= 6T^{-1} \frac{M \ln(M/L)}{M - L} ((M/L)^{1/n} - 1)^2.
\end{align*}
\]

Hence (5.15). Similarly, (5.16) follows by noting that, when \(H(x, y) = -T^{-1} \ln^2(y/x)\), the conditions of Lemma H.1 hold with

\[
\begin{align*}
  a(x) &= -\frac{2}{x^2} T^{-1}, \\
  b(y) &= -\frac{2}{y^2} T^{-1} (1 + \ln(M/L)), \text{ and} \\
  w &= 2T^{-1} (2 + \ln(M/L)) ((M/L)^{1/n} - 1)^2.
\end{align*}
\]
I Calculation of $\pi_{\inf}([0, M])$ for Variance Swaps

We first show the following propositions.

**Proposition I.1.** Assume that $\{0, M\}$ is acceptable. Then, for any $L \in [0, \delta_0(0, M)/2]$, $\{L, M\}$ is acceptable, and $\delta_0(L, M) \geq \delta_0(0, M)/2$.

**Proof.** Using the same notation as in Definition 5.1, with the same techniques as in the proof of Theorem 5.3.

The second equation follows from (I.1). Thus, for $F, S, k, x$, and so $\delta_0(L, M) \leq S - c_{i,j} \leq K_{i,j}$.

The second equation follows from (I.1). Thus, for $L \in [0, \delta_0(0, M)/2]$, if the value of $k_1$ changes from 0 to $L$, $wc_{i,j} + (1 - w)c_{i''}j''$ diminishes by at most $L$. Hence, (5.2) still holds if $k_1 = L$ and $k_1 = M$, and $\delta_0(L, M) \geq \delta_0(0, M) - L$. This concludes the proof.

**Proposition I.2.** Let $F$ be a subset of $\mathbb{R}^+$, $x_0$ an element of $F$, and $F'$ a finite subset of $F$ that contains $F \cap [x_0, \infty)$. Let $g$ be a function on $F$ and $\lambda$ a real number such that, for any $z \in F$,

$$g(z) \leq g(x_0) + \lambda(z - x_0).$$

Then, for any element $x$ of $F \cap (x_0, \infty)$, $\overline{g}_{F'}(x) = \overline{g}_{F \cap [x_0, \infty]}(x)$, and there is a real number $\xi^*$ such that, for $z \in F$,

$$g(z) \leq \overline{g}_{F \cap [x_0, \infty]}(x) + \xi^*(z - x).$$

**Proof.** Proof. Let $x$ be any element of $F \cap (x_0, \infty)$. By Proposition 4.3, there is a real number $\xi^*$ such that (I.3) holds for $z \in F \cap [x_0, \infty)$. In particular,

$$g(x_0) \leq \overline{g}_{F \cap [x_0, \infty]}(x) + \xi^*(x_0 - x).$$

On the other hand, (I.2) implies that $\overline{g}_{F \cap [x_0, \infty]}(x) \leq g(x_0) + \lambda(x - x_0)$, and so, by (I.4), $\xi^* \leq \lambda$. Thus, by (I.2), $g(z) \leq g(x_0) + \xi^*(z - x_0)$ for $z \in F \cap (0, \infty)$ which, together with (I.4), implies that (I.3) holds for $z \in F \cap (0, \infty))$. Hence, (I.3) holds for any $z \in F$, and so $\overline{g}_{F'}(x) \leq \overline{g}_{F \cap [x_0, \infty]}(x)$. But, since any concave function that upper-bounds $g$ on $F'$ also upper-bounds $g$ on $F \cap [x_0, \infty)$, we conclude that $\overline{g}_{F'}(x) = \overline{g}_{F \cap [x_0, \infty]}(x).$}

We now show how to calculate $\pi_{\inf}([0, M])$. Given $n > 0$, set

$$F' = K \cup \{\frac{j}{n}M, j \in \{1, \ldots, n\}\}.$$
**Theorem I.1.** Assume that \( \{0, M\} \) is acceptable. Let \( B = m T^{-1} \ln^2(4M/\delta_0(0, M)) \). Then, for \( n \geq 4M/\delta_0(0, M) \), \( \pi_{\inf}(F') \) can be calculated in \( O(N(1^3 + n^2 m + l m n)) \) total time with precision \( \epsilon \) via the convex program (3.3), where

\[
N = O\left( I \ln \left( \frac{I(1 + S_0)(1 + B)}{c_0(0, M)} \right) \right),
\]

and \( V' \) has a separation oracle that runs in \( O(n^2 m + l m n) \) time. Furthermore,

\[
\pi_{\inf}((0, M]) - \pi_{\inf}(F') = O(n^{-2}). \tag{I.5}
\]

**Proof.** Let \( H(x, y) = -T^{-1} \ln^2(y/x) \). Since \( \psi \leq 0 \), it follows from (E.1) that Assumption A1 holds in the market \( M_m(F') \), with

\[
q = B + S_0 \sqrt{l} \text{ and } \delta = \delta_0(0, M)/4.
\]

Since the spacing between two consecutive elements of \( F' \) is at most \( \delta_0(0, M)/4 \), there is a real number \( k_* \in F' \cap [\delta_0(0, M)/4, \delta_0(0, M)/2] \). By Proposition I.1, \( \{k_*, M\} \) is acceptable and \( \delta_0(k_*, M) \geq \delta_0(0, M)/2 \). On the other hand, as \( 0 \leq |\psi| \leq B \) in the market \( M_m(F' \cap [\delta_0(0, M)/4, M]) \), by Proposition 5.1, Assumption A2 hold in this market. Since any risk-neutral probability in a sub-market of \( |M_m(F')| \) is also a risk-neutral probability in \( M_m(F') \), we conclude that A2 holds in the market \( M_m(F') \) as well. Finally, an argument similar to that in the proof of Theorem 5.3 shows that A3 holds in the market \( M_m(F') \), with \( T = O(n^2 m + l m n) \). This shows the first part of the theorem.

We now show (I.5). Let \( L_i = \min(K)e^{-(m-i)\sqrt{\ln M}} \) for \( 1 \leq i \leq m \), and let \( L_0 \) be the largest element of \( F' \cap [0, \min(K)e^{-m\sqrt{\ln M}}] \), which is non-empty if \( n \) is sufficiently large. Assume that \( \beta = (b_1, \ldots, b_m) \) is such that \( ||\beta||_\infty \leq R_0 \). Define \( \tilde{c}_i(x) \) for \( x \in (0, M) \) by setting \( \tilde{c}_m = 0 \) and, for \( 0 \leq i \leq m - 1 \), \( \tilde{c}_i(x) = 0 \) if \( x \in (0, L_0] \), and, for \( x \in (L_0, M] \),

\[
\tilde{c}_i(x) = \sup_{Q \in Q(x,F')} E_Q(\tilde{c}_{i+1} + H_{i+1}(x,.)). \tag{I.6}
\]

(I.6) is obtained from (5.17) by replacing \( c_i, c_{i+1}, F_0 \) with \( \tilde{c}_i, \tilde{c}_{i+1}, F' \) respectively. For \( y > 0 \) and \( 1 \leq i \leq m \), every component of \( f_1(y) \) is at most \( y \), and so \( b_i f_1(x) \geq -l_i R_0 y \). Hence \( H_i(x, y) \leq l_i R_0 y \), and so it follows by backward induction that, for \( x \in (0, M] \) and \( 1 \leq i \leq m \),

\[
\tilde{c}_i(x) - b_i f_i(x) \leq l_i R_0 x. \tag{I.7}
\]

We show by backward induction that, for \( 1 \leq i \leq m \), \( x \in (0, L_{i-1}] \) and \( z \in (0, M] \),

\[
\tilde{c}_i(z) + H_i(x, z) \leq 0. \tag{I.8}
\]

Assume first that \( i = m \), and let \( x \in (0, L_{m-1}] \). Then (I.8) holds if \( z \leq L_m \) since \( f_m \) is null on \( (0, L_m) \). On the other hand, if \( z \in (L_m, M] \), then \( H(x, z) \leq -l R_0 M \), and so, by (I.7), (I.8) holds again in this case. Thus the induction hypothesis holds for \( i = m \). Assume it holds for \( i + 1 \). By (I.6), it follows that \( \tilde{c}_i(x) \leq 0 \) for \( x \in (0, L_i] \). Assume now that \( x \in (0, L_{i-1}] \). Since \( H(x, z) \leq -l R_0 M \) for \( z \in [L_i, M] \), (I.7) implies that (I.8) holds for \( z \in [L_i, M] \). On the other hand, (I.8) also holds for \( z \in (0, L_i] \) since \( f_i \) is null on \( (0, L_i] \). Thus the induction hypothesis holds for \( i \).

Let \( x \in (0, L_0] \cap F' \). It follows from (I.8) that the RHS of (I.6) is at most 0. But, by considering the probability \( Q \) supported on \( \{x\} \), it can be seen that the RHS of (I.6) is non-negative, and is thus null. Hence (I.6) holds for \( x \), and so it holds for any \( x \in F' \). Thus, an argument similar to the proof of (H.5) shows that \( \tilde{c}_0(S_0) = c(\Psi; M_m(F')) \).
Set
\[ L' = \frac{L_0}{e + \ln(M/L_0) + lR_0TL_0}, \]
and let \( L \) be the largest element of \( F' \cap [0, L'] \), which is non-empty if \( n \) is sufficiently large. Fix \( x \in (L_0, M] \) and \( i \in [0, m-1] \), and let \( g(z) = \tilde{c}_{i+1}(z) + H_{i+1}(x, z) \). We show that, for \( z \in (0, M] \),
\[ g(z) \leq g(L) + (z - L)g'(L). \]
(I.9)

Note that \( g(z) = H(x, z) \), for \( z \in (0, L_0] \), and so (I.9) holds in this case because, by (H.6), \( H(x, \cdot) \) is concave on \((0, L_0]\). On the other hand, for \( L_0 < z \leq M \),
\[ g(L) + (z - L)g'(L) = T^{-1}(2(\frac{z}{L} - 1) - \ln(\frac{x}{L}))\ln(\frac{x}{L}). \]
But
\[ 2(\frac{z}{L} - 1) - \ln(\frac{x}{L}) = 2(\frac{z}{L} - 1) - \ln(\frac{z}{L}) - \ln(\frac{M}{L}) \]
\[ \geq \frac{z}{L} - 1 - \ln(\frac{M}{L_0}) \]
\[ \geq lR_0Tz. \]
The second equation follows from the inequality \( \ln(y) \leq y - 1 \), and the third equation holds for \( z \geq L_0 \) by standard calculations. Thus
\[ g(L) + (z - L)g'(L) \geq lR_0z, \]
which, together with (I.7), implies (I.9). Thus (I.9) holds for \( z \in (0, M] \).

Let \( \tilde{F} = (0, L] \cup F' \). By (I.9), and since \( \tilde{F} \cap [L, M] \subseteq F' \subseteq \tilde{F} \), we can apply Proposition I.2 with \( F = \tilde{F} \), \( x_0 = L \) and \( \lambda = g'(L) \). Hence, by (I.6),
\[ \tilde{c}_i(x) = \sup_{Q \in Q(x, F' \cap [L, M])} E_Q(\tilde{c}_{i+1} + H_{i+1}(x, \cdot)), \]
and there is a real number \( \xi_{i,x}^* \) be such that, for \( z \in \tilde{F} \),
\[ \tilde{c}_{i+1}(z) + H_{i+1}(x, z) \leq \tilde{c}_i(x) + \xi_{i,x}^*(z - x). \]
Since \( \tilde{c}_{i+1} \) is null on \([L, L_0]\), arguments similar to those used in the proof of Theorem 5.3 (see (H.3), (H.7) and (H.8)) show that, for \( z \in (0, M] \),
\[ \tilde{c}_{i+1}(z) + H_{i+1}(x, z) \leq \tilde{c}_i(x) + \xi_{i,x}^*(z - x) + w, \]
(I.10)
where \( w \geq 0 \) and \( w = O(n^{-2}) \).

On the other hand, by (I.8), (I.10) holds for \( x \in (0, L_0] \) if we set \( \xi_{i,x}^* = 0 \), and so it holds for \( x \in (0, M] \). We infer that, in the market \( \mathcal{M}_m((0, M]) \),
\[ \Psi \leq \tilde{c}_0(S_0) + \sum_{i=1}^m \xi_i(S_i - S_{i-1}) + mw, \]
where \( \xi_i \) is the financial derivative \( \xi_i = \xi_{i,S_{i-1}}^* \). Hence,
\[ c(\Psi; \mathcal{M}_m(0, M]) \leq c(\Psi; \mathcal{M}_m(F')) + mw. \]

We conclude the proof using Proposition F.1.

In practice, \( \pi_{\inf}(F') \) can be calculated for any integer \( n \) such that \( \{M/n, M\} \) is acceptable. Numerical calculations of \( \pi_{\inf}(F') \), using the same setting as in Table 5, are given in Table 14. The prices in Table 14 are very close to \( \pi_{\inf}(F_0) \) in Table 5.
 Remainder of the proof of Theorem 5.4

We say that a real-valued function $g$ defined on a set of real numbers $W$ is $\kappa$-Lipschitz on $W$ if $|g(x) - g(y)| \leq \kappa |x - y|$ for $x, y \in W$.

**Lemma J.1.** Let $g$ be a real-valued bivariate function defined on $[L, M]^2$ such that, for some constants $\kappa_x$ and $\kappa_y$, for any $x, y \in [L, M]$, the functions $g(., y)$ and $g(x, .)$ are respectively $\kappa_x$-Lipschitz and $\kappa_y$-Lipschitz on $[L, M]$. Let $W$ be a finite subset of $[L, M]$ that contains $\{L, M\}$ and $\mu$ the maximum distance between consecutive elements of $W$. For $x \in [L, M]$, set

$$h(x) = \sup_{Q \in \mathcal{Q}(x, W)} E_Q(g(x, .)).$$

(J.1)

Then $h$ is $(\kappa_x + \kappa_y)$-Lipschitz on $[L, M]$. Furthermore, for any $x \in [L, M]$, there is a real number $\xi^*$ such that, for $y \in [L, M]$,

$$g(x, y) \leq h(x) + \kappa_y \mu + \xi^*(y - x).$$

(J.2)

**Proof.** Fix $y, y' \in W$ with $y < y'$. For $x \in [y, y']$, let

$$F(x, y, y') = \frac{(y' - x)g(x, y) + (x - y)g(x, y')}{y' - y}.$$  

Since, for $y < x < x' < y'$,

$$(y' - y)(F(x', y, y') - F(x, y, y')) = (x - y)(g(x', y') - g(x, y')) +$$

$$(y' - x)(g(x', y) - g(x, y)) + (x' - x)(g(x', y') - g(x', y)),$$

it follows after some calculations that the function $x \mapsto F(x, y, y')$ is $(\kappa_x + \kappa_y)$-Lipschitz on $[y, y']$.

Fix now two consecutive elements $y_0$ and $y_1$ of $W$. By Proposition 4.3, the probability $Q$ in (J.1) can be assumed to be supported on two points $y$ and $y'$ of $W$ and so, for $x \in [y_0, y_1]$,

$$h(x) = \max_{y, y' \in W, y \leq y_0, y_1 \leq y'} F(x, y, y').$$

Since the maximum of a finite set of $\kappa$-Lipschitz functions on $[y_0, y_1]$ is $\kappa$-Lipschitz on $[y_0, y_1]$, it follows that $h$ is $(\kappa_x + \kappa_y)$-Lipschitz on $[y_0, y_1]$. Thus, $h$ is $(\kappa_x + \kappa_y)$-Lipschitz on any interval delimited by consecutive elements of $W$, and so it is $(\kappa_x + \kappa_y)$-Lipschitz on $[L, M]$.

By Proposition 4.3 and (4.9), there is a real number $\xi^*$ such that $|\xi^*| \leq \kappa_y$ and, for $z \in W$,

$$g(x, z) \leq h(x) + \xi^*(z - x).$$

(J.2) follows since, for any $y \in [L, M]$, there is $z \in W$ within distance $w/2$ from $y$.

</table>
For \( \nu \geq 0, 0 \leq i \leq m \), and \( x, y \in [L, M] \), let \( \zeta_\nu(x, y) = \sqrt{\nu^2 + \ln^2(y/x)} \). Define by backward induction the functions \( \tilde{c}_i(\nu, x) = \tilde{c}_i(\nu, x, \beta) \), for \( \nu \geq 0 \), \( x \in [L, M] \), and \( 0 \leq i \leq m \) by setting \( \tilde{c}_m(\nu, x) = \min(\nu, \nu_{\max}) \) and, for \( 0 \leq i \leq m-1 \), \( \nu \in \Lambda \),
\[
\tilde{c}_i(\nu, x) = \sup_{Q \in Q(x,F_0)} E_Q(g_{i+1,\nu}(x,.)),
\]
where
\[
g_{i,\nu}(x, y) = \tilde{c}_i(\zeta_\nu(x, y), y, y) - b_i^T f_i(y),
\]
and, for \( \nu \in \mathbb{R}^+ - \Lambda \),
\[
\tilde{c}_i(\nu, x) = (1 - \lambda)\tilde{c}_i(\rho(\nu), x) + \lambda \tilde{c}_{i+1}(\rho(\nu + \nu_{\max}/n'), x),
\]
where \( \lambda = (\nu - \rho(\nu))/(\nu_{\max}/n') \). (J.3) can be thought as the limit of (5.25) as \( n' \) goes to infinity, while (J.5) says that \( \tilde{c}_i(\nu, x) \) is calculated by linear interpolation for \( \nu \in [0, \nu_{\max}] - \Lambda \), and is set to \( \tilde{c}_i(\nu_{\max}, x) \) for \( \nu \geq \nu_{\max} \). As the function \( \nu \mapsto \sqrt{\nu^2 + a^2} \) is 1-Lipschitz for any constant \( a \), and since the supremum and the weighted average of 1-Lipschitz functions is 1-Lipschitz, it can be shown by backward induction that \( \tilde{c}_i(\nu, x) \) is 1-Lipschitz and non-decreasing with respect to \( \nu \) and, for \( \nu \in \Lambda \) and \( x \in F_0 \),
\[
c_i(\nu, x) \leq \tilde{c}_i(\nu, x) \leq c_i(\nu, x) + \frac{(m - i)\nu_{\max}}{n'}.
\]
We now prove the following.

**Lemma J.2.** For \( \nu \geq 0, x \in [L, M] \), \( 0 \leq i \leq m \), the function \( g_{i,\nu}(x, .) \) is \( \kappa_i \)-Lipschitz on \([L, M]\), where
\[
\kappa_i = \frac{2(m - i) + 1}{L} + \Sigma_{j=1}^m \|b_j\|_1.
\]

**Proof.** We prove the lemma by backward induction. The induction hypothesis holds when \( i = m \) since the derivative of \( \zeta_\nu(x, y) \) with respect to \( y \) is at most \( 1/y \), and any call function is 1-Lipschitz. Assume it holds for \( i+1 \). Since \( \tilde{c}_{i+1}(., y) \) is 1-Lipschitz and the derivative of \( \zeta_\nu(x, y) \) with respect to \( x \) is at most \( 1/x \), for \( y \in [L, M] \), the function \( g_{i+1,\nu}(x, ) \) is \((L^{-1})\)-Lipschitz on \([L, M]\). Also, by the induction hypothesis, the function \( g_{i+1,\nu}(x, ) \) is \( \kappa_{i+1} \)-Lipschitz on \([L, M]\), for \( x \in [L, M] \). By Lemma J.1 and (J.3), it follows that \( \tilde{c}_i(\nu, .) \) is \((L^{-1} + \kappa_{i+1})\)-Lipschitz on \([L, M]\) if \( \nu \in \Lambda \). By (J.5), the same conclusion holds for any \( \nu \geq 0 \). On the other hand, by (J.4),
\[
|g_{i,\nu}(x, y') - g_{i,\nu}(x, y)| \leq |\tilde{c}_i(\zeta_\nu(x, y'), y') - \tilde{c}_i(\zeta_\nu(x, y), y')| + |\tilde{c}_i(\zeta_\nu(x, y), y') - \tilde{c}_i(\zeta_\nu(x, y), y)| + |b_i^T (f_i(y) - f_i(y'))|.
\]
The first term in the RHS of (J.7) is at most \( L^{-1}|y' - y| \) since \( \tilde{c}_i(., y') \) is 1-Lipschitz and \( \zeta_\nu(., .) \) is \((L^{-1})\)-Lipschitz. The second term is at most \( (L^{-1} + \kappa_{i+1})|y' - y| \) since \( \tilde{c}_i(\nu, .) \) is \((L^{-1} + \kappa_{i+1})\)-Lipschitz. The last term is at most \( \|b_i\|_1|y' - y| \) since any call function is 1-Lipschitz. Hence
\[
|g_{i,\nu}(x, y') - g_{i,\nu}(x, y)| \leq \kappa_i|y' - y|,
\]
and the induction hypothesis holds for \( i \). \( \Box \)

Let \( w = L((M/L)^{1/n} - 1) \). It follows from Lemmas J.1, J.2 and (J.3) that, for \( x \in [L, M], \) \( 0 \leq i \leq m \), and \( \nu \in \Lambda \), there is a real number \( \xi_{i,\nu,x} \) such that, for \( y \in [L, M] \),
\[
g_{i+1,\nu}(x, y) \leq \tilde{c}_i(\nu, x) + \kappa_1 w + \xi_{i,\nu,x}(y - x).
\]
Since \( \tilde{c}_{i+1}(., y) \) is non-decreasing, it follows that, in the market \( \mathcal{M}' = \mathcal{M}_{m}([L, M]) \),
\[
\tilde{c}_{i+1}(\nu_{i+1}, S_{i+1}) - b_{i+1}^T f_{i+1}(S_{i+1}) \leq \tilde{c}_i(\nu_i, S_i) + \kappa_1 w + \xi_{i,\nu_i,S_i}^*(S_{i+1} - S_i).
\]
Define the financial derivative $\xi_{i+1} = \xi^*_i R_i S_t$. By summing up (J.8) for $i \in [0, m-1]$, we get

$$
\Psi' \leq \tilde{c}_0(0, S_0) + m\kappa_1 w + \sum_{i=0}^{m-1} \xi_{i+1}(S_{i+1} - S_i).
$$

Thus,

$$
c(\Psi'; M') \leq \tilde{c}_0(0, S_0) + m\kappa_1 w.
$$

Assume now that $\beta = (b_1, \ldots, b_m)$ is such that $||\beta||_{\infty} \leq R_0$, and let $\kappa = 2L^{-1} + lR_0$, so that $\kappa_1 \leq m\kappa$. By (J.6) and, since $c_0(0, S_0) = c(\Psi'; M)$, where $M = M_m(F_0)$, it follows that

$$
c(\Psi'; M') \leq c(\Psi'; M) + \frac{m\nu_{\text{max}}}{n'} + m^2\kappa w.
$$

Hence, by Proposition F.1,

$$
|\pi_{\text{sup}}(\psi', \phi; M') - \pi_{\text{sup}}(\psi', \phi; M)| \leq \frac{m\nu_{\text{max}}}{n'} + m^2\kappa w.
$$

On the other hand, by (5.19),

$$
|\pi_{\text{sup}}(\psi, \phi; M')\sqrt{T} - \pi_{\text{sup}}(\psi', \phi; M')| \leq \frac{m\nu_{\text{max}}}{n'}.
$$

Thus,

$$
|\pi_{\text{sup}}(\psi, \phi; M')\sqrt{T} - \pi_{\text{sup}}(\psi', \phi; M')| \leq 2\frac{m\nu_{\text{max}}}{n'} + m^2\kappa w.
$$

Since, by (5.24), $R_0 = O(1)$, this implies (5.22). We can show (5.23) in a similar manner.

## K Robust pricing of Volatility swaps via linear interpolation

Even though $\tilde{c}_0(0, S_0)$ does not appear to have a simple financial interpretation, we can use it rather than $c_0(0, S_0) = c(\psi' - \beta^T \phi; M)$ in order to calculate the super-replicating price of a volatility swap. This yields the following algorithm. By analogy to (2.4), let

$$
\hat{V}' = \{(\beta, \gamma) \in \mathbb{R}^d \times \mathbb{R} : \tilde{c}_0(0, S_0, \beta) \leq \gamma, \beta^T \pi + \gamma \leq q + 1\},
$$

where $q$ is given by (5.24), and

$$
\pi_{\text{sup}}(n, n') = \inf_{(\beta, \gamma) \in \hat{V}'} \beta^T \pi + \gamma.
$$

We use a cutting plane algorithm to minimize $\beta^T \pi + \gamma$ over $\hat{V}'$. We construct a separation oracle for $\hat{V}'$ by analogy to that of $V'$ in Proposition 3.1, as described below. Using Proposition 4.3, we calculate by backward induction $\tilde{c}_i(\nu, x)$ for $\nu \in \Lambda$, $x \in F_0$ and $0 \leq i \leq m-1$, and probabilities $\hat{Q}(\nu, x, i)$ that maximise the RHS of (J.3). Given a call option $\tilde{\eta}$ with maturity $k \leq m$ and payoff $\tilde{\eta}(S_k)$, define the function $\tilde{\eta}$ by backward induction on $\mathbb{R}^+ \times F_0$, $0 \leq i \leq k$, by setting $\tilde{\eta}_k(\nu, x) = \tilde{\eta}(x)$ and, for $0 \leq i < k$, $\nu \in \Lambda$, and $x \in F_0$,

$$
\tilde{\eta}^*_i(\nu, x) = \mathbb{E}_{\hat{Q}(\nu, x, i)}(\eta^*_i(\sqrt{\nu^2 + \ln^2(z/x)})),
$$

and, for $\nu \in \mathbb{R}^+ \setminus \Lambda$,

$$
\tilde{\eta}^*_i(\nu, x) = (1 - \lambda)\eta^*_i(\rho(\nu), x) + \lambda \eta^*_i(\rho(\nu + \nu_{\text{max}}/n'), x),
$$

where $\lambda = (\nu - \rho(\nu))/(\nu_{\text{max}}/n')$. We construct a separation oracle for $\hat{V}'$ by replacing $c(\psi - \beta^T \phi)$ with $\tilde{c}_0(0, S_0)$ and $E_P(\phi)$ with the vector $(\eta^*_0(0, S_0))$, where $\eta$ ranges over the components of $\phi$, in the algorithm described in Proposition 3.1.
are computed in time proportional to the number of traded days \( m \) that satisfies (6.1) and such that Theorems 5.3 and 5.4.

Proof of Theorem 6.1

L  Computing times for variance and volatility swaps in terms of the number of periods

This section uses the same settings as in Subsections 5.2 and 5.3. Tables 15 and 16 list the optimal super-replicating and sub-replicating prices for variance and volatility swaps, for fixed \( l, n \) and (for volatility swaps) \( n' \), with maturities ranging from 1 to 8 months. These prices are computed in time proportional to the number of traded days \( m \), which is consistent with Theorems 5.3 and 5.4.

M  Proof of Theorem 6.1

Let \( (\beta^a, \beta^b, \gamma) \in V'' \). By the assumptions of the theorem, there is a risk-neutral probability \( P \) that satisfies (6.1) and such that

\[
-q \leq E_P(\psi) \\
\leq (\beta^a - \beta^b)^T E_P(\phi) + \gamma \\
\leq (\beta^a)^T (\pi^a - \delta 1_l) - (\beta^b)^T (\pi^b + \delta 1_l) + \gamma \\
= (\beta^a, \beta^b)^T ((\pi^a, -\pi^b) - \delta 1_{2l}) + \gamma,
\]

where the second inequality follows from (2.6). Hence, for \( 1 \leq i \leq 2l \),

\[
-q \leq (\beta^a, \beta^b)^T ((\pi^a, -\pi^b) \pm \delta e_i) + \gamma,
\]

and so \( V'' \subseteq \mathcal{E}'(2l, (\pi^a, -\pi^b), q, \delta) \). Thus (6.2) follows by arguments similar to those in the proof of Lemma 3.1.

Consider now a vector \((\beta^a, \beta^b, \gamma) \in \mathbb{R}^{2l} \times \mathbb{R} \) that belongs to the ball of radius \( r \) centered at \( u = (r 1_{2l}, q + \delta) \). Since \( ||\beta^a - r 1_l|| \leq r, ||\beta^a|| \leq r \) and \( \beta^b \in \mathbb{R}^{+l} \). By the triangular inequality, \( ||\beta^a - \beta^b|| \leq 2r - \delta \). Furthermore, \( q \leq \gamma \) since \( |q + \delta - \gamma| \leq r \leq \delta \). Thus, by Assumption A1 and (2.4), \((\beta^a - \beta^b, \gamma) \in V\). On the other hand, since \((\beta^a, \beta^b, \gamma - q - \delta) = (\beta^a, \beta^b, \gamma) - u + r (1_{2l}, 0)\), \( ||(\beta^a, \beta^b, \gamma - q - \delta)|| \leq r + r \sqrt{2l} \). As

\[
a_0^T (\beta^a, \beta^b, \gamma) = a_0^T (\beta^a, \beta^b, \gamma - q - \delta) + q + \delta,
\]
it follows from the Cauchy-Schwartz inequality that $a_0^T(\beta^a, \beta^h, \gamma) \leq 3r\sqrt{l}\|a_0\| + q + \delta$. Thus $a_0^T(\beta^a, \beta^h, \gamma) \leq q + 1$, and so $(\beta, \gamma) \in V''$. The rest of the proof is similar to that of Proposition 3.1. □
